THE SITUATION PSYCHOSIS.

By JOHN E. LIND, M.D.,

WASHINGTON, D. C.

CLINICAL DIRECTOR, SAINT ELIZABETH'S HOSPITAL.

THE classification of mental disorder has this in common with other branches of medicine, that it is more or less arbitrary, subject to great differences of opinion, frequently changing, and seldom rational in the last analysis. It differs, however, in that it is more arbitrary, subject to greater differences of opinion, always changing, and never rational. From the days of Hippocrates, who recognized dementia, excitement, and depression, down to Ziehen, who subdivides each of his fifty-seven varieties of insanity into a thousand parts, there has scarcely ever been a prominent worker in this field who has not thought it necessary to modify the classification of mental disease according to his own ideas.

It may, therefore, seem a work of supererogation to suggest an addition to the list of names of mental disease; and yet in recent years we have come to recognize a type of disease which is certainly as distinct an entity as, we will say, toxic psychosis. Where on the one hand a toxemia may produce a psychosis in a predisposed individual, on the other hand an unbearable situation by its psychical trauma may have a like effect; and just as the toxic psychosis usually clears up with the cure of the toxemia so does the situation psychosis get well when the individual is taken out of the causative situation.

We may define a situation psychosis as a transitory mental disorder caused in a predisposed individual by an unbearable situation and curable usually by the removal of that situation.

The use of the word "predisposed" in this definition requires a word of explanation. It does not mean predisposed in the same sense that the ordinary psychopathic type is predisposed, but in a way which is not as a rule sufficient to act as a handicap in the ordinary affairs of life. In many of these patients a faulty heredity is found, but extensive studies along this line will be necessary before any justifiable conclusions can be formulated. Some of these patients are defective mentally, varying from a type sometimes seen, measuring only eight or ten years by intelligence tests, to others only slightly subnormal, so little so that their defect seems to interfere but slightly, if at all, with earning power. One fairly constant characteristic of the type of person who develops a situation psychosis is the possession of weak inhibitions and autochthonous emotional fluctuations. These people are easily influenced temporarily for good or bad; they recognize right and wrong and the ethical desirability of the former, but are unable to make any determined resistance to temptation. They are easily elated and depressed, become angry from trivial causes, and in general show an unstable emotional reaction. Besides this type of individual there are others who show definite precox or manic-depressive make-ups. In these the symptomatology of the situation psychosis follows the pattern of the functional psychosis, but is less complete and more transitory. It is this sort of patient who is responsible for the diagnosis we have been seeing in the reports of insane hospitals in recent years—"Allied to Dementia Precox," and "Manic-like Reactions." A diagnosis of this kind means either a lack of diagnostic acumen or a situation psychosis.

A word as to the precipitating and immediate causes of the situation psychosis. As in most psychoses there is a precipitating event or situation, but in the situation psychosis this is something outside the individual, and which he cannot influence, alter, or remove by his own effort. For example, in the precox we often see a love-affair, undue pressure at school or work, loss of a parent, fright, strain, etc., act in bringing on the upset. In other words, the episode which is the immediate cause of the psychosis arises to some extent from the actions of the patient himself, or at any rate he finds himself in a situation which he can alter or remove or from which he can escape. Scarcely a combination of events similar to those just outlined can be imagined from which an individual cannot escape, and that too without seeking refuge in a psychosis, provided he is not bound by any too strict ethical observances; and the type of individual we have in mind is seldom, if ever, thus bound. But the situation as we are using the term in the situation psychosis is one created by society at large and not amenable to the will of the individual himself. Of course, it may be said that he has freedom of choice originally and can avoid the situation, but this is not strictly true, as will be shown presently. And once having gotten in the toils he has no escape except in a psychosis.

The chief two situations which arise in society as at present constituted are prison and military environment. So we see the situation psychosis arising in camps and prisons. In the one case a predisposed individual drifts into the Army, enamored of the tinsel aspect of militarism, and in the other case he commits some crime, either impulsively or because he finds it easier to steal than to work for

a living. But, however he may come within the prison or barracks, he finds himself restricted on every side by rules and regulations, enforced by strict punishments. As he is totally unable to adapt himself to such a severe régime he breaks down. In either case we have a potent factor, non-operative in ordinary life, and that is fear. In the Army or Navy we have the fear of being sent to the front and killed and in the prison we have the fear of the death-sentence, of life-imprisonment, and in many cases, notably murderers, there is the fear of punishment after death which is present in the conscience of the most hardened criminal, no matter what attitude he assumes ostensibly. We can divide, therefore, for purpose of study, the situation psychosis into two groups, resembling each other in many respects, but having important points of difference. They are the prison psychosis and the military psychosis.

THE PRISON PHYCHOSIS

A brief history of the prison psychosis will give us some perspective on the subject. (The information is obtained entirely from "The History of the Prison Psychoses," by Wilmanns and Nitsche, translated by Barnes and Glueck.)

No especial attention appears to have been paid to mental disorder developing in prison until the middle of the nineteenth century. In 1853 Delbruck called attention to the large percentage of mental disorders occurring in the inmates of Halle prison. He pointed out some interesting correlations between the nature of the crime and the psychosis. Crimes of violence, he said, affect the mind of the prisoner much more deeply than those against property, they cause delusions of justification, innocence, and pardon, while it is rare for the criminal against property to develop a psychosis at all, and if he does it is likely to be as a result of long-continued or unduly harsh imprisonment.

In 1862 Gutsch added somewhat to the knowledge of the subject; he believed that a deficient previous education was favorable to the development of mental disturbance as these individuals lacked resources and hence easily became bored and depressed. He stated that 3.3 per cent. of the uneducated prisoners developed psychoses while only 1.08 per cent. of the educated ones did. He attached a great deal of importance to somatic factors, the debilitating influence of the deprivation of fresh air, good food, and abundant exercise, and particularly solitary confinement with limited food and in darkness. He also pointed out the strong clinical similarity which most of these psychoses developing in prison bore to each other and thus was the first to shadow forth the prison psychosis.

In 1884 Sommer published the results of his studies of all the cases which were transferred from various prisons and penitentiaries to the insane asylums at Allenberg during the period of thirty years. He found in seventy-five per cent. of these cases a predisposition to mental disease on account of alcoholism, imbecility, weak inhibitions, etc. He called attention to the fact that mental disease was less prevalent in institutions where prisoners associated freely with each other or were in the open a good deal. Thus of thirteen cases received by him from reformatories eight had been definitely suspicious even before conviction. He found that the man who is sent to prison for a crime committed in an impulsive or passionate moment was twice as likely to develop mental disorder as the habitual criminal, and that the long-term prisoner was three times as susceptible as the short term one. He gave the name of "prison paranoia" (*Gefängnisswahnsinn*) to the form of mental disorder which he observed most frequently and gave a clinical description of its course.

In 1881 Moebi called attention to a peculiar state of mind sometimes occurring in prisoners awaiting trial where the mental faculties would seem entirely confused and yet on examination the individual appeared to have some idea of his environment. For example, if he were shown a quarter he would call it a nickel; if an envelope, paper; shoes, stockings; and so on. Later on Ganser described this condition more fully and after him it is usually called "Ganser's symptom-complex"; he pointed out that the symptoms mentioned by Moebi were only part of the picture, which also includes hallucinations, analgesias, and amnesias.

The next work of importance was done by Rüdin in 1890, who reported ninety-four cases; he divided them into four classes: (1) The actual psychoses, seen only incidentally in prison; (2) The vagabond type; (3) The habitual criminal; (4) The occasional criminal. He found Ganser's symptom-complex in forty-five per cent. of his patients.

In 1907 Siefert made a contribution to the subject in which he takes what is essentially the present-day attitude. He divides the psychoses occurring in prisons into two classes, the degenerative prison psychoses and the true psychoses. In eighty-seven cases which he studied he found fifty-four of the former and thirty-three of the latter. The real prison psychosis, he says, occurs most frequently in the third decade of the life of a habitual criminal. Characteristics which predispose toward it are changeability and irritability of temper, emotional mobility—dependent but little on external circumstances—and tendency to day-dreaming and subjectivity of environment. He over-elaborated his scheme of classification, however, by dividing these psychoses into six types: hysteriform, simple, phantastic, paranoid, simulated, and demented.

Nowadays there are two views held by prison physicians: one that the psychoses occurring in prison do not differ essentially from those of the outside world (with such minor variants as the substitution of prison guards for police, masons, etc., in the paranoid types), and the other following the school of Magnan and Moebius, that is, that the prison psychosis is the result of what might be called a degenerative diathesis plus the peculiarly restricting nature of a prison environment. As a matter of fact these two views are not irreconcilable, for both types of psychoses do occur in prison.

The course of the typical prison psychosis is on lines somewhat as follows: A man who has never gotten into any trouble with the law, although perhaps not of a high type intellectually and accustomed to indulge himself, kills someone in a burst of passion, and is thrown into prison awaiting trial. Here he is assailed on the physical side by rigid

restrictions, backed up by stern disciplinary measures, and on the psychical side he has to endure the pangs of conscience coupled with the fear of punishment. It is noted that his ordinary behavior changes, he becomes morose, suspicious, irritable. He starts when someone enters his room. He is seen to look behind him occasionally and is heard pacing the floor of his cell at night. Next may come an acute delirious episode, during which he tears things to pieces, gesticulates, laughs, and sings. Following this, he goes into a delusional state, which may become chronic. *His delusions relieve in some way the distressing situation.* Thus he may have the idea that his victim is still alive, that he himself has been pardoned, or he may rise above the petty considerations of crime and punishment by developing grandiose ideas. The further course of the psychosis depends upon the disposition of the patient: a removal from prison may result in a prompt return to normal, while on the other hand continuance of the prison environment may cause a permanent condition with deterioration.

Illustrative of the clinical forms which prison psychoses take it might be well to quote a few cases here.

Case I.—F. T. This is a colored laborer who shot another man during a quarrel and was later indicted for murder, as his victim died. Shortly after being placed in jail he became violent and noisy, had vivid hallucinations, talked constantly, and attacked the guard. This excitement subsided, but he went into a chronic delusional state which has persisted, with little or no change at the time of writing, two years and a half. His delusional ideas are two-fold in character: He thinks that his victim is not dead, saying that he has never seen the dead body and he knows they would have shown it to him if he had really killed a man and he believes that "mind-readers" are acting on him, taking his thoughts away from him. This latter sounds, of course, very much like the delusions of dementia precox, and, indeed, the patient himself may turn out to be a precox, but he lacks any of the other symptoms of the disease. Furthermore, the fact that he was an efficient individual economically before being arrested, that his breakdown occurred in prison immediately after the emotional shock of finding himself in danger of being tried for murder, the clinical course of an acute delirious episode, followed by subsidence into a delusional state, with compensatory ideas, and the lack of the introversion symptoms which we would expect to see in precox (the patient's personality shows no signs of disintegration), make us hesitate to make a diagnosis of dementia precox. No doubt, too, a release would be followed by a rapid clearing up of the picture.

Case II.—W. M. (The abstract of this case is taken verbatim from "Studies in Forensic Psychiatry," by Bernard Glueck.) This patient came from a good family and led a normal life, earning a substantial livelihood as printer up to the age of about thirty-eight. At this time one of his children died and this, together with poor physical health, is said to have brought on a severe depression, during which he was actively suicidal and very self-accusatory. Several months later he lost another child by fire, and at this time also claimed to have obtained positive proof of his wife's infidelity. His depression became aggravated; he attempted suicide on a number of occasions, was very suspicious and apprehensive, developed persecutory delusions, feared he was going to be burned to death or suffer some other horrible fate. This condition finally necessitated his admission to the Government Hospital for the Insane, on May 28, 1897, at the age of forty. Here he gradually improved, and was discharged into the care of his father on October 22, 1899. On February 19, 1903, he was readmitted as a prisoner, having shot and killed a man who seduced one of his daughters. Not being able to face reality, he annihilates it and substitutes for it a world created out of fantasy, in which he plays every conceivable rôle but the real one, *i.e.* that of a patient accused of murder. We will see that he does this by the mere fiat of his word, that magic dexterity which has served so well primitive man in his struggle with reality. Illustrative of his grandiose ideas are the following letter and check, of which he produces several daily:

"Senator Blank: The United States Senate was here some time ago and gave me your name to write to for verified release to come over Monday and accompany me to Washington. I have already been there a few times. They want you to come for me. I have never committed any crime and rescued you once from being a drowned man at River View, Md. Yours, W. H. M."

"U. S. Treasury, Pa. Ave. and 15th St., Washington, D. C., October 15, 1914. Please pay to King George of England Ten Thousand Dollars for professional services, $10,000. W. H. M."

Thus by the mere stroke of a pen he, a poor mortal accused of murder and indefinitely confined in an institution, succeeds in putting himself in touch with King George, in drawing *ad libitum* upon the United States Treasury, in ridding himself of the wife whom he accuses of infidelity, and in annihilating old age (he calls himself forty-one now, although he is in reality sixty-one and looks seventy). His belief in these statements is absolutely unshakable, notwithstanding the fact that he retains a clear orientation concerning his immediate environment, and thus has the actual state of his affairs constantly forced on his attention. His grandiose compensation has such dimensions as to gratify every imaginable wish of his. He came here because he was divorced from his wife, not because of any crime he had committed. He is the son of the supervisors in charge of this building. He owns this institution and built it for a place in which he could count his money. He has forty-eight wagon loads of this. He will live 250 years, because he has taken the severest punishment to secure this. He refuses to assist with the ward work, because he pays $1.50 a day for board, and is not supposed to do any work. He was brought here to select a woman for his wife. They brought him a lot of blue-eyed blondes and also a lot of Baltimore and St. Louis beauties, etc.

Case III.—G. N. This patient is an Armenian. Family history unreliable. States himself that he studied three years for the priesthood and was an exceptionally good student, but quit voluntarily because he thought he might want to marry some day. Information obtained from other sources is that patient was expelled from a theological seminary on account of escapades with women. Little is known about his adventures in this country except that he was associated with a gang of blackmailers and seems to have been the "brains" of the gang. As a result of their persecutions of a wealthy Armenian they ran afoul of the Postoffice Inspectors and G. N. received sentences amounting to eight years. In the penitentiary he is recorded as having delusions of persecution, thinking that his food was doped; he also had a transitory attack of excitement and delirium. When admitted to St. Elizabeth's Hospital he told of having been doped in prison and for a few months after admission formed somewhat similar ideas about the hospital; that is, he would complain that the milk given him tasted peculiar and that molasses was placed on his chair in the dining-room. He soon developed the delusion which he still has at the time of writing this, the idea that he has been pardoned. He states that as he was being brought here on the train he saw his pardon papers in the hands of the guard with him, and when he reached the supervisor's office here the latter asked for the papers in his case, saying there seemed to be none. It is evident that the patient misinterpreted some actual remarks of the supervisor, but he refuses to be convinced of this. He has been shown commitment papers, but claims they were issued in error. He has also been allowed to send registered letters to the judge and clerk of the court where he was tried, to the superintendent of prisons, to the warden of his prison, and several other officials, and though all these have replied that there was no error in his sentence, and that no pardon had ever been granted, the patient persistently refuses to accept this overwhelming evidence, but

continues to maintain that he has been pardoned and is being denied the benefit of it by trickery and fraud. This patient is a highly emotional, unstable neurotic. He passes from extreme elation to deep depression in the course of a few minutes, is easily angered, is fond of stirring up trouble among the less intelligent patients and is in turn resigned, sarcastic, cheerful, bitter, and lacrymose. On one occasion he was visited by the inspector largely responsible for his conviction. He began to talk to this official quietly enough, but soon worked himself up into a towering rage, cursed, threatened, and gesticulated, and finally in a theatrical manner left him, threatening that he would get even with him "if it took a lifetime."

Case IV.—M. C. A colored male, aged thirty-three, who is serving a life sentence for murder in the second degree. Very little information is obtainable about his heredity, and this little is negative. As far as can be ascertained he never had any serious physical disease, with the exception of gonorrhea at the age of nineteen, which lasted two months, and was followed by stricture. His school life lasted from the fifth to his sixteenth year. He has been a laborer, and also learned the barbering trade, which he gives as his occupation. He has never married and nothing abnormal sexually can be learned. He drank beer and whisky freely and has been intoxicated on a number of occasions. Twice before his present trouble he was arrested and convicted of minor offenses.

In 1907, at a negro picnic, he became involved in a quarrel with another Negro over a woman, and a bystander essayed the rôle of peacemaker. The patient had an open knife in his hand, with which he was cutting meat, and in the scuffle stabbed the peacemaker, who afterwards died. The patient was tried, convicted, and sentenced to life imprisonment. He arrived at the Leavenworth penitentiary in 1907.

The exact time of the onset of his psychosis unfortunately cannot be learned, as the prison record obtained with him gives scant information on this subject. It merely shows that he was admitted to the psychopathic ward there October 20, 1912, and that "for some time previous to that he had been under observation on account of erratic behavior." This behavior, as nearly as can be learned, was:

He called the attention of the prison physician to a tattoo mark on his hand, and stated that he believed that he was not a Negro, but painted black. He also expressed ideas to the effect that he had built a number of prisons and railroads, that the warden owed him $40,000, that he was a detective, an author, etc.

The ward notes made by the attendant in the psychopathic ward in the prison are mostly statements that he "wanders in his talk." We also learn that on October 21, "Claims that he built this prison, that it is an exact duplicate of the Capitol Building at Washington." October 22, "Says he built all prisons and railroads in this country." October 26, "Says he must get out as he has a contract to build a big railroad." October 27, "Says he has a secret paint which he can use that will turn him white." Here, as nearly as can be learned, is the second expression of the delusional idea which later becomes so prominent. He is now groping about, as it were, for satisfactory refuge from the world of reality, and hits upon this secret paint. Later, as we shall see, this does not suit his purpose, and the idea is modified. November 8, "Says he has a contract to build a prison in Washington, D. C., and is waiting for his railroad contracts to be signed." November 10, "Says he has poisoned water in his cell. Can kill a million people." This is the last note made on the patient in prison, as he was shortly afterwards transferred to this hospital, but while in the psychopathic ward he wrote two letters to the warden and the prison physician, in which he referred to the money the warden owes him, the contracts which await his signature, and states, "I left some oil in a can in the storeroom that will take this paint off."

M. C. arrived at this hospital December 6, 1912. The physical examination was negative, with the exception of some fine tremors of the tongue, eyes, and fingers, the urine analysis was negative, and the Wassermann reaction with the blood serum was negative. Examination of the cerebrospinal fluid was negative in every respect.

A mental examination made shortly after his admission showed the following (the scheme in White's "Outlines of Psychiatry" was used): Patient was accurately oriented in all spheres. He was neither depressed nor elated, but appeared rather impatient to be put in communication with his white relatives and friends that he might take his place in the world again. No hallucinations were obtained. There was absolute lack of insight. Memory and intelligence did not appear to be impaired. The whole psychosis seemed to consist of a confused mass of delusional ideas, the most constant of which were those about his color. He stated that he had assumed his present disguise a number of times in the past in order that he might mingle freely with the Negroes to carry out certain business and political projects. He had also adopted, so to speak, a Negro family of the same name as his own, and when he was wearing this disguise he lived with them the more completely to fool people.

Other delusional ideas which do not seem to play as prominent a part are that his victim did not really die, but only simulated death; that he built a town called Washington, in Louisiana, exactly resembling the Capitol City, and that there he was a leading citizen; that he built numerous prisons and railroads, that he "immigrates," as he expresses it, people to parts of the South, West, etc.

The physicians' notes made on this patient during the year and a half he has been an inmate of the Government Hospital for the Insane, have shown little or no change in him. He has perhaps become more unintelligible, especially lately, when more determined efforts have been made to uncover the mainsprings of his psychosis. He has been at all times a quiet, well-behaved patient, has assisted with the ward work, and associated freely with the other patients.

Practically every morning he accosts the physician on his rounds and makes some request relative to his main delusional idea. Now he wants a half a pound of Epsom salts with which to bleach himself, again some fish-oil which may remove the paint, etc.

He is quite a prolific letter writer; his productions are directed to presidents of banks, merchants, and other prominent men in Washington, and a town in Virginia where he formerly lived, requesting "that they come up here and identify him as a white man." The following from a letter addressed to the doctor, is quite typical:

"Preface:

"I am perfectly that you could ignore the fact that I has this paint own myself and that I would hafter to stay here a long time if you did not tess it for me the fact is if a hospitle is not a place to tess such a thing as a disguise I don't know the place that is I have been here tenn months and have spok to each Doctor about the Disguise and know that I have had dealing with each one of them that would make them perfectly aware of the fact you would not look this over carefully and give me some."

During the past few months many efforts have been made to get in communication with this patient, but his defenses are so many that these have been of little avail.

In addition to the information given above, the following features of the case may be of interest:

He says that the time he committed the crime he had on the black paint. He says he had himself painted black because the colored people had him tangled up in certain laws he had made, so he wore the paint for a disguise. He further states that he was doing some work for Lincoln and didn't want people to recognize him.

He has known thousands of white women and men, and has rescued white people from the Indians.

Concerning his crime, he says he knows that the man isn't dead because twice before he saw the same man in the morgue laid out for dead.

An effort was made to get at the mechanism of this patient's psychosis by his dreams, but little could be done along this line. He did say that he had dreamed of being with white women and men whom he knew, but attempts at analysis were futile.

One hundred word associations were tried with M. C., but instead of giving a reaction word he evidently picked out objects about the room and gave them at

random to the stimulus words, as table, pen, ink, cuspidor, etc. Then the list was repeated, but in no instance was the same reaction word given. The average time was 2 1/10 seconds, but it should be noted that the reaction time to "Negro" was seven seconds, and to "paint," nine seconds. The reaction word to "cover" was "milk" (possibly an association of milk with the perfect white), the reaction time was four seconds, and it was reproduced as "paint." To "paint," after nine seconds came "scrape," reproduced as "brother." To "Negro" was given "watch," reproduced as "window."

So as we sum up this case and try to understand the forces which have been at work to produce such a grotesque delusional field and such apparent dilapidation of ideas, we are confronted with several difficulties. The two chief are, first—the inadequate history of the inception of the psychosis, and second—the present inaccessibility of the patient. We can at best but give what appears to be the explanation.

We will picture to ourselves, then, M. C. as he was seven years ago, a fairly typical Negro, loving the physical excitements of life, as his race does, the warm sunshine, the catchy music, the alcoholic glow, the vivid color, the one hundred and one things which make existence happy for the Negro in the summer time He goes to a picnic, there is a brawl, and presto! he has killed a man. Swiftly succeed the jail, the court room, the convict train, and the penitentiary. He is now a murderer, doomed for the rest of his days to be shut away from all which made life enjoyable to him.

How long a period passed before his adjustment to the scheme of things began we do not know. It was over four years before his lack of harmony with his environment was sufficiently obvious to his jailers to make them suspect mental disorder. Probably there was a period during which his being was benumbed, so to speak, by the blow which had fallen. Before he began to react to the reality which had suddenly closed in on him there was a time when his vital forces were stunned, the shock was too tremendous to be believed, at first, and he laid it aside for future and fuller consideration. Then, too, during the first year or so of his imprisonment there may have been hopes which died hard. He may have cherished the idea that he would find some way of escaping, or that the powers that be would realize that his sentence was too severe and mitigate it or pardon him entirely.

But as the months grew into years he sees these faint hopes fade away, and at last he is face to face with reality, the reality of a lifetime in prison. He must accept it or battle with it. He refuses to accept it, but resists it, and gradually he changes reality.

As we see him to-day, he is living in the world that he has created about himself, the universe of which he is the center, the "*Deus ex machina*." If we cannot orient ourselves in this dream world, it is because the patient alone possesses the open sesame to its mysteries. Around his city he has thrown a wall of unintelligibility; if we try to talk to him now we find he speaks another language than our own, he coins new words, and gives utterance to phrases and sentences which have no apparent meaning and no place in the context. This is his final and most effective protection from reality.

Briefly, then, the patient has compensated himself for reality in three main ways:

First, he is not a murderer, because his victim is still alive.

Second, he is not imprisoned for murder because he himself built and owns the prison.

Third, he is not the Negro imprisoned for murder, because he is a white man disguised as a Negro.

The first of these compensations he does not seem to have elaborated to any great extent, and I think this is due to certain racial characteristics. A white man under similar circumstances would be apt to choose the simplest defense to a charge of murder, the "*corpus delicti*" of the law, *i.e.* there had been no murder committed, but the victim simply feigned death. In the Government Hospital for the Insane we have a beautiful illustration of this in a murderer who has built un a complete delusionary field practically on this one idea. But this simple explanation does not suit the Negro, just as in a law court a Negro is not satisfied to deny a fact by one plain contradictory statement, but must discourse at length on the reasons why he is not guilty—like the lady in the play, he is inclined to protest too much.

The second method of compensation presents much more detail, as does the third, probably because they are founded on complexes which have existed from earliest childhood, the poverty complex, and the color complex. In reality they may almost be called one complex, for he evidently symbolizes superiority by the color white.

There is perhaps a fourth method of compensation which seems to be a comparatively late development, and is not yet fully elaborated. As nearly as can be understood, the whole thing is a case of mistaken identity, due to the fact that there is a town in Louisiana called Washington (this is really the case, but the same thing is true of most states, and the town of Washington, Louisiana, is evidently very small, judging from the information I have been able to obtain), which the patient built and where he is a prominent citizen, etc. Through some mischance he has been confused with another man of the same name, a poor Washington Negro, who has committed a murder. If his townspeople in Washington, Louisiana, can be notified, the error will be rectified.

So as we see our patient to-day he is entrenched behind four rows of defences which shut out the world of reality effectively, and within which he finds life bearable. Around the outer breastworks, so to speak, of his defences, he has constructed a maze of unintelligibility in which we who attempt to penetrate to his psychic secrets find ourselves wandering dazed in a labyrinth of neologisms, irrelevances, and digressions. Now and then we catch a glimpse of the world in which the patient lives, and then another turn shuts out the view and we find ourselves groping in the dark.

How long this individual would have continued in what Jelliffe calls the "predementia period" it is impossible to say; perhaps he would have entered one of the services, and the rigid requirements of military discipline would have caused the defence reaction of his psychosis. Perhaps there would have been a gradual development of the psychosis without other direct causes than the duties of daily life. But as it was he was suddenly brought face to face with reality in its most insistent aspect, and after a certain amount of refusal to see and to believe he developed his psychosis which solves for him his problem.

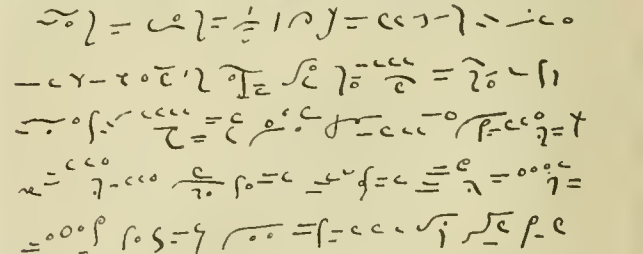
Case V.—L. C. White male, aged 29 on admission. Father was tubercular, mother nervous, maternal aunt and cousin insane. Patient was said to have had some convulsive seizures at the age of two, to have been a nervous child, and to have suffered from frequent headaches. As a young man he worked for a druggist, where it is noticeable that he often quarreled with his employer and quit, returning a day or so later. He served one enlistment in the Marine Corps, but re-enlisted in the cavalry, being attracted by the novelty and liking horses. In June, 1909, about eight or nine months after enlistment, he was tried by summary courtmartial for firing ahead of time on the target range and fined $20. He considered this unjust, and brooded over it. He also claims to have found the society of the men in his troop uncongenial; they were from the East Side of New York, and spent all their spare time lying about, cursing, swearing, and smoking cigarettes. He asked Captain R. for permission to buy out, but this was refused. Then he asked for a transfer and the captain refused this. Shortly after this he went to town on a pass extending from 7 P.M. Saturday to 7 P.M. Sunday. His own account of the events following is as follows: He drank a little during Saturday evening, and took a room in a hotel for the night. On awakening Sunday morning he found he had but 18 cents, instead of $2.18, as he had supposed. He had several drinks while thinking over this circumstance, and came to the conclusion that a certain Private F. had stolen the $2. He started to return to the post, and met a newsboy selling papers telling about a shooting affray the night before, in which a soldier had been wounded. He bought a paper, and reading this account put the idea of shooting in his head. (On one occasion the patient said that the paper he bought was blank.) He returned to the post, went

to his locker, took out a revolver and five rounds of ammunition, went to the basement and loaded his gun. At this time, he says, if he had met Private F. he would have shot him. Some one then told him that Captain R. wished to see him. On reporting, the captain inquired why he had overstayed his pass, and patient said his pass extended to 7 P.M. The captain had the first sergeant look up the application, and found that the company clerk had erroneously written 7 A.M. The duty sergeant further reported that the patient had been seen tearing off his chevrons (he was a corporal) downtown the previous evening, which the patient denied. These two unjustified accusations made the patient angry, and when the captain said, "That is all, Corporal," he replied, "Sir, I would like the captain's permission to resign as a non-commissioned officer. Captain R. said, "Very well, that will do, Corporal, that is all." The patient then stepped back a pace, saying, "No, it isn't all, Captain," drew his gun and began firing. The first sergeant and the company clerk were but slightly wounded, the captain was shot in the neck and died ten days later. The patient was then put in solitary confinement and later on the colonel informed him that the captain had died. For one month he believed this, was depressed and repentant, and didn't care to live. Then he began to have headaches, and his food tasted as if it were doped. A month or so after this he began to believe that the captain was not dead, and that he was being "framed up." He became furiously angry about this. On admission to St. Elizabeth's Hospital he had elaborated this idea considerably. He said that Captain R. was only slightly wounded and "played dead," and was now having a good time and persecuting him. He said that wadding had been substituted in the cartridges for lead so that no harm could possibly have been done the captain. He said that an elaborate mock funeral was held to further the deception. As illustrative of the tenacity with which he held this delusion may be mentioned this incident: A letter was read by the hospital authorities from the murdered man's father, stating that he was satisfied from all that he had heard that the murderer was insane. The patient was told of the existence of this letter, but refused to believe it, so it was shown to him. He read it carefully, studied its signature, date, and physical appearance, finally shrugged his shoulders, and returned it, saying that it was not genuine, and that the captain was not dead. Much emotionalism was shown at this interview, and he was upset for some time after it.

During his whole stay in the St. Elizabeth's Hospital, a period of three years and three months, he maintained these delusions. He left four years ago, and the further history of his case is unknown. It appears that through some legal chicanery he was taken away from guards who were removing him to an asylum in another State, and he has been home with his family since then. Several letters which have been received since his departure by inmates who had been friendly with him show no signs of mental trouble, but it is not known positively whether or not he has the same delusional ideas.

CASE VI.—A. G. This patient is an adult male, thirty-some years of age, and of mixed race, probably three-fourths negro and one-fourth Spanish. Little or nothing can be learned about his family or previous personal history, as he has no relatives living near at hand, and his own mental condition has precluded an accurate anamnesis. It appears, however, that when about sixteen years of age he served six months in prison for breaking the seal on a box car. Six years later he served two years in the penitentiary for assault with a dangerous weapon. Shortly after this he killed a man in New York, was found insane, and sent to Matteawan, where he stayed five months, recovered and was discharged. (An effort has been made to obtain a history of his case while there, but as he used a false name, and as he refuses to give adequate information about this time of his life, it has proved impossible.)

He then came to Washington to live, and contracted a liaison with a mulatto woman. Shortly afterwards he discovered that she had been unfaithful to him, and determined to kill her. He armed himself with a razor, and laid in wait for her. About dusk she was returning home, having just left her paramour, when the patient sprang out, seized her and threw her on her back. He then deliberately cut her throat from ear to ear. (It happened that the writer saw his victim shortly after the assault: the head was nearly severed from the body, and the cut extended into the cervical spinal column, cutting into the cord itself.) He was shortly afterwards arrested, tried, and sentenced to death. After this the first symptoms of mental disorder appeared. He told the guards he was Jesus Christ. The writer saw him just before and just after these symptoms appeared, and had no doubt in his mind that he was malingering. Many things contributed to this belief. The patient showed no unusual behavior when he thought that he was not being observed, but when he noticed some official looking at him steadily he at once began to act, overdoing his part considerably, making absurd gesticulations, picking up bits of earth and putting them in his mouth. Questions by the doctor were answered in a way which would seem to indicate the most extreme confusion, but the patient's general behavior and his conversation with other prisoners were what might have been expected of a person clearly oriented. In court he refused the services of a lawyer, cried out that he wanted to be hung, and cursed the presiding judge. A motion for a new trial on the ground of insanity was denied and he was returned to jail, where the same symptoms continued. He was brought into court and sentenced to be hanged, whereupon he sprang up and shouted that he was Jesus Christ, and could not be hung. He was then sent to St. Elizabeth's Hospital for mental observation, where it was decided that he was malingering, and he was returned to jail with this report. A motion for a new trial was again denied and he was again sentenced to be hanged. It appears that the judge who sentenced the patient had serious doubts of the man's sanity, in spite of the official report, and undoubtedly intimated to the powers that be that he would not be averse to seeing sentence deferred until the question was settled to the satisfaction of every one. At any rate, reprieve after reprieve was granted, and finally he was pardoned. He was then sent to St. Elizabeth's Hospital, arriving here July 26, 1913, and is still here. On the occasion of his second admission to the hospital those physicians who remembered him from his first admission noticed a change, not easy to define, but conveying the impression that his mental state had passed from that of malingerer to an actual psychotic. His conduct was more consistent, he showed bizarre actions even when he could not know that he was observed, his dress grew slovenly, etc. He began to collect rubbish and stuff his pockets with it, and ate soap and dirt at times. He also demanded paper and pencil at all times and covered the former with writing (see the illustration) somewhat like ancient Egyptian. When asked to read this he would jabber away a meaningless jargon, in which some Spanish words could be detected. In the past five years he has grown gradually more and more dilapidated mentally. Now he is



filthy in his habits, disoriented in all fields, talks and laughs at times in an irrelevant, disjointed manner, and at other times jabbers in his manufactured language. He seldom uses the written language now, except when especially requested to do so, and then he will write a few lines of it only. It appears that this patient, alarmed at the grave fate which impended, feigned mental illness, and the strain of this continued malingering proved too much for a mind not especially well balanced, causing an actual psychosis, which has now progressed to a point where recovery is extremely

improbable, even under the most favorable circumstances.

Thus in the above cases we see several different ways in which the psyche may take refuge from an unbearable situation. In Case I a murderer believes that his victim is not dead and explains his imprisonment and the uneasy thoughts which struggle for entrance into his mind by attributing them to experiments carried on by mind-readers. Case II, another murderer, develops an excessively grandiose delusional system—secure in a world of his own where he is fabulously wealthy, he forgets his troubles. The fact that he cannot get out is dismissed carelessly either by saying that he came here to get a registered letter or a check cashed and is being held until he can be identified or by saying that he has lost his key. Case III, a blackmailer, believes that he has been pardoned that he will be discharged as soon as this is proved. Case IV, a murderer, thinks that he is a white man painted black and hence confused with a colored man of the same name and made to suffer for his crimes. Case V, a murderer, thinks his victim is still alive and plotting against him, which is the reason he is kept in prison so long. Case VI, another murderer, is somewhat similar to Case II, but being a lower type of mentality has deteriorated much more rapidly.

It will be noticed that of the six cases selected somewhat at random five happened to be murderers, and it is true that there is an extremely high proportion of this class among those suffering from prison psychoses. We must seek an explanation for this in the extreme obliquity attributed to the murderer by both religious and secular laws. Back of this is of course the instinct of self-preservation.

A man then who has taken a human life, no matter under what provocation, has to bear the reproaches of his own conscience, the fear of legal punishment and the dread of a retribution even after death. He, especially among men, is placed in an unbearable situation, so it is small wonder that many of them erect a psychotic defense.

THE MILITARY PSYCHOSIS

The type of psychosis we see peculiarly in army camps has very much in common with the prison psychosis, but some important differences must be noted. The differences are: First, that the etiological situation is much more bearable to most persons because it is only a temporary situation, and no matter how bad things are the soldier can look forward to a discharge at the end of his enlistment, and if lucky he may get out in less time by purchase, through illness, or feigning. While the prisoner has in most cases to look forward to death, life-imprisonment, or a long term and he has no hope of getting out sooner except by the unlikely method of breaking prison. Then, too, we have in the prisoner the sense of guilt, while the mind of the soldier is animated more or less strongly by patriotism and hope of glory. One difference, however, must be added to the other side of the balance. The prisoner, leaving aside for the moment those awaiting trial or under sentence for murder, is in no personal danger, while the soldier, especially during war time, may at any moment be put on active duty and be either wounded or killed.

Even before the recent war cases of military psychosis developed sporadically. Men who enlisted in the army while intoxicated or out of work or under the influence of a temporary impulse, found themselves in an environment which meant hard work and rigid discipline. Many of them, being temperamentally unable to adapt themselves to these exacting conditions, developed defense reactions very similar to those of the prison psychosis. The most common sort of military psychosis is, however, a paranoid state with ideas that the other soldiers are calling the patient vile names. This is probably an explanation of the patient's unconscious for the fact that he cannot get along as well as the other men in the company: because they are "down on him" and try to injure him in various ways.

Illustrative of the reactions which we see in this form of psychosis are the following cases:

Case VII.—J. K. This is a twenty-two-year-old white male, who was drafted into the army April 26, 1918. Before that time there had been no suspicion of mental disorder of any kind. His family history was entirely negative. After several months' training he was sent to England, was there two weeks, and went to France. Shortly after this he went to the front, and was there about five days when he wandered away. He was discovered some distance from his company in a confused state, and sent to a base hospital. After being there about a month without improvement he was sent back to the United States, and after being detained in a general hospital a short time he was sent to St. Elizabeth's Hospital.

When admitted here he appeared in good condition, was well oriented, accessible, and manifested no hallucinations or delusions. When asked what had been the matter with him it appeared that he had amnesia for the time of his illness, said he must have been insane, because he could not think; said he felt a little weak, and could not sleep well, but otherwise was all right.

The patient's physical condition improved, and after a month or so he was discharged and sent home to his family.

Case VIII.—J. P. This is a twenty-seven-year-old white male, admitted to the hospital October 24, 1918. His family history was negative. He was born in Ireland and came to the United States at the age of twenty-two. He had had a good education, and since leaving school had been a farmer. He enlisted in the army shortly after the declaration of war, went to France in September, 1917, and in January went to the front line trenches. Three months later he was sent to the hospital for mental observation. The reasons for this, as far as can be ascertained from information available, were that from being gay and lively he had become sad and depressed, sat by himself a great deal, and was seen talking to himself. When admitted to the base hospital in France he showed a lack of interest in his surroundings, and impairment of attention and retention; questions required many repetitions to elicit answers. The patient showed emotional deterioration and heard voices talking to him, would pray for his relatives every day, including many that were dead.

When admitted to St. Elizabeth's Hospital this patient showed none of the symptoms described in the French hospital. He was accessible, cooperated well, and had no hallucinations or delusions. When relating the circumstances of his mental episode he said that he must have been insane, but it did not appear that he recalled the hallucinations from which he suffered nor in reality did he appreciate the fact that his conduct had been unusual. After being retained in the hospital for several months he was discharged.

Case IX.—W. R. This is a twenty-three-year-old white male. He was admitted to St. Elizabeth's Hospital, January 8, 1919. His family history is negative. He had a common school* education, and after leaving

*In the sense this expression is used in this paper it is the completion of the graded schools, but no high school education.

school had worked as a laborer in a pulp mill. He was selected for service in the army in August, 1918, and a couple of months later was sent to France. He was there two months, but never reached the firing line. Shortly after landing he complained of pain in the face and stomach, and constant headache. Said the water did not agree with him, and that he could not eat or sleep. He became nervous, and was sent to a base hospital, where he remained two weeks and was then returned to the United States. At the base hospital he appeared somewhat elated, talked excessively, but showed no hallucinations or delusions. On reaching the United States he seemed somewhat confused, was retarded in his answers, and said that he heard voices calling him by name. These voices also mentioned his brother's name, and at times abused him, calling him "bastard" and other bad names.

When admitted to St. Elizabeth's Hospital he had recovered from his hallucinations, and claimed he had no recollection of them. He appeared cheerful, was well oriented, and had no complaints to make except of an occasional pain about his heart (physical examination was absolutely negative). He had no insight, stating that he believed he had never had any mental trouble, but that he must have had neuralgia. After several months he was discharged and returned to his family.

Case X.—F. D. This is a twenty-three-year-old white male, who was admitted to St. Elizabeth's Hospital December 31, 1918. Family history was negative. Patient had a common school (*v.s.*) education, with a few weeks in high school. He got along well at school and at home, and after leaving school he became a file clerk in a business firm and was promoted through various grades until he became bookkeeper, which position he held about six years, leaving it to enlist in the army in August, 1917. In November of the same year he went to France, and apparently got along well there for seven months, when he was sent to the hospital for a contused wound inflicted by falling with a large piece of meat in his hands. (He was serving in the Quartermaster Corps.)

A detailed anamnesis of him in the French hospital brought out the following facts: Just before his accident he had been transferred from near the front and had been given unusually hard manual labor. His company was situated so that it was particularly subject to attack by hostile aeroplanes, and on one occasion one of his comrades was killed and several others wounded by bombs. This occurred at night, and in the morning he helped to move the dead and wounded. This incident turned his thoughts upon the danger to which they were exposed, and he began to realize for the first time that the camp was poorly protected. He placed but little reliance on the anti-aircraft guns which were situated one or two miles away from the camp. He noticed, moreover, that his captain slept in the cellar of a certain house, while he and the other men slept on the upper floors, and were consequently in danger of aeroplane attacks, while the captain was well protected. He began to brood over various things about this captain, as for example that he drank a great deal, and on one occasion left his company to sleep in the stable, while he went to town and got drunk, also that a number of officers—both commissioned and non-commissioned—had been transferred because they failed to get along with this captain.

About this time he began to have curious experiences. He saw a man go into a restaurant in the town near the camp and come out again half an hour later with an American Red Cross kit on his shoulder. He appeared to be an escaped German prisoner. He attempted to follow this man, but lost track of him. One night when he was unable to sleep he saw a Frenchman enter the kitchen, and got the idea that he was going to steal something, so took his pistol, arrested him, and turned him over to the sergeant. In short, it appears that his condition at the time he was admitted to the French hospital was that of a paranoid state, arising in a neurotic individual. It was also reported that his pupils were widely dilated ,and he had a fine constant tremor of the fingers.

When he was admitted to this hospital he had recovered from these symptoms, although he had but little insight into his condition. He attributed his breakdown to worry over his mother's health and insomnia due to noises, partly those of the camp itself, and partly those which the enemy aeroplanes made. After one month he was discharged.

It seemed quite evident that when he enlisted in the army he expected to make his way up to a commission as he had been promoted rather rapidly in business. He failed in this, however, and partly as a result of this failure and partly from a fear which became an active motivating force when he got near the front, he developed a paranoid state. He got himself out of this situation somewhat neatly by dropping a piece of meat upon his leg, causing himself to be sent to a hospital. It is not difficult to suppose that this action was unconsciously motivated. At any rate, it served the purpose adequately, for after being sent to the hospital his mental symptoms became evident, and he was transferred back to the States, where he cleared up rapidly.

Case XI.—F. D. An eighteen-year-old white male, admitted to the hospital October 24, 1918. His paternal uncle had some mental trouble of unknown nature. Patient had a fairly good education, and after leaving school went to work, helping his father, who kept a small store. He enlisted in the army in January, 1918, and went to France two months later. He did not get to the front, but after several months began to worry about home, suffered from insomnia, and feared that he was going to be hit by a shell. This condition came on him gradually and was accompanied by a feeling of nervousness and fatiguability. He had auditory hallucinations, which did not become articulate as voices, but which he describes as "a sort of underground noise." He was sent to the base hospital, and from there back to the United States.

When he reached this hospital he was practically normal in his reactions, but somewhat depressed, had no hallucinations or delusions, and did not think there was anything wrong with his mind. The only explanation he could give for his upset was that he got nervous from being away from home, and could not sleep. He was a well-behaved patient, and showed no symptoms while here except that he appeared to be of a neurotic makeup, and was emotionally somewhat unstable. During a severe thunder storm, for example, he got very nervous. He suffered from insomnia part of the time while at this hospital, and was depressed until his discharge was in sight, when he became more cheerful.

Case XII.—M. C. This is a twenty-three-year-old white male admitted to the hospital, December 19, 1918. The mother was very nervous, and suffered from tuberculosis. One uncle is suffering from a mental disorder of a nature not known. Patient is the son of a well-to-do coffee planter in Porto Rico. He never had but two years formal education, although he had much instruction of a general and informal nature, and was far from illiterate. He has always worked, helping his father.

In July, 1918, he enlisted in the army at Porto Rico, and was sent to Panama. A month or two later it was observed that he seemed depressed, losing interest in his duties, and finally ceasing to talk at all. He was sent to the hospital, where he was entirely mute. When addressed he would point to his mouth, apparently meaning he was unable to talk. He also had a practically complete anesthesia. It was later learned that before his mental symptoms had become obvious he told some one that he had shot himself through the ear some time ago and this bullet was lodged in his brain, causing all the trouble.

He was transferred from the hospital at Corozal to St. Elizabeth's Hospital, and when admitted here had recovered his speech and gave a fairly normal reaction. No hallucinations or delusions were obtained and he had good insight into his condition, stating that he must have had mental trouble of some sort, but that he did not know what caused it nor could he explain any of the symptoms which he showed. He was thought to be a hysteric who enlisted in the army under the influence of a temporary impulse, and when he found himself in the military situation developed a psychosis resembling catatonic precox with some hysterical features.

Case XIII.—L. S. This tweny-two-year-old negro soldier was admitted to the hospital December 1, 1918. The family history was negative except that two sisters

and one brother died of tuberculosis, and father was addicted to alcohol. Patient is the son of a laborer, and has had only a few years' education. After leaving school he worked on the farm for his father and continued at this until selected for service in the army, July 19, 1918. About two months later he developed an excitement, concerning the origin of which we have no definite information. He himself states that he was rejected for duty in a powder plant on account of physical weakness following influenza. He was so disappointed over this that he began to cry, and was seen by a lieutenant, who sent him to the hospital. This made him excited. It seems probable, however, that the excitement was due to his being assigned to duty at this powder plant, which the patient naturally thought of as unusually hazardous. At the hospital he was completely disoriented, very much excited, and it was necessary to restrain him. This lasted several days, and then he went into a stuporous state. He had both visual and auditory hallucinations at the post hospital, but when he arrived at St. Elizabeth's Hospital these were not in evidence. He showed amnesia for the period when he was at the post hospital.

The above cases illustrate partially the sort of reaction we find in this branch of the situation psychoses. The writer has not come into such close personal contact with these military cases as with the prison psychoses, but it is evident that they have much in common. The points of difference are dependent upon the differences between the military situation and the prison one. The prison environment, *e.g.* may be a very long, even a life-long, affair, and hence the prison psychosis may assume a state of chronicity which does not occur in the disorders seen in soldiers.

The military psychoses quoted need little comment. Case VII shows a young boy taken from civilian life who found himself after a short period of training at the front. He developed an acute confusional state which showed little improvement even after he was sent to a base hospital. It was only when he was on his way back to the United States that he began to recover. Case VIII under somewhat similar etiological circumstances showed an episode, precox-like, with introversion symptoms, which gradually improved after removal from the front and finally ended in recovery. Case IX showed first elation, then depression; there were also hallucinations of an abusive nature. Case X had made fairly good progress in civil life, but did not do so well in the army. His reaction was a paranoid state which ended in recovery. Case XI was evidently caught early, showed prodromal symptoms, which would undoubtedly have developed into auditory hallucinations. Case XII showed mutism and a complete anesthesia, with delusions, in other words, he was a hysteric who developed a precox episode under stress. Case XIII is a negro, who, when confronted with extra hazardous duty, became excited and confused.

Summary.—A situation psychosis is a transitory mental disorder caused in a predisposed individual by an unbearable situation over which he has no control. The two principal forms are prison and military psychoses, these two environments being the situations most commonly arising in civilized society, from which there is no escape. The predispositions which exist are such things as tainted heredity, defective mentality, emotional instability, drug addictions, faulty education, etc.

The prognosis is usually good. With the pardon of the prisoner, or his removal to a more favorable environment, or in the case of the soldier, his withdrawal from the military situation, the symptoms clear up fairly rapidly. In some cases, however, where there was an extremely fertile soil, or where the patient remained too long in the situation, or where perhaps certain aspects of the situation, *i.e.* the ethical ones, were not susceptible of modification, a more or less permanent disorder resolves itself out of the acute symptoms of the onset, and the patient shows a mental picture resembling somewhat closely that of a case of dementia precox.

The treatment is first of all, preventive. No recruit should be accepted for enlistment without an investigation of his antecedents, his past life, together with a complete mental examination, including an estimate of his intelligence by one of the standard schemes. Military surgeons should be instructed and persuade the line officers to be on the lookout for evidences of beginning mental disorder, changes in disposition, complaints about other men, etc. *Any attempt to evade military duty by self-mutilation is sufficient reason for a thorough mental examination of the offender.* Psychiatrists should be freely consulted when prisoners show changes in behavior; observation wards, apart actually and in spirit from the prison proper, should be established, and suspicious cases isolated and studied.

These are only sketchy suggestions. The main thing is the recognition of these predisposed types, knowledge of the prodromal symptoms, and an early and intelligent handling of the patients. While the possibility of malingering is never to be forgotten, it must be borne in mind that it is relatively infrequent and that while little harm is done by putting an impostor in an observation ward for a time, much and perhaps irreparable damage may be done by continuing to apply the rigidities of prison or military discipline to a psychescent mind.

DOES THE CURE OF CANCER DEPEND UPON OXIDIZATION OF THE TISSUES?

By EDWARD PERCY ROBINSON, M.D.

NEW YORK.

THE eternal problem of cancer seems to be near solution. We are arriving at analogous results obtained from sources differing in their etiology yet representing one phenomenon. In the past few months three instructive articles on the treatment of cancer by radium, by *x*-rays and by actinic rays have appeared in our medical literature, by men

working independently in these respective fields. All three report curative results almost identical in character. In not one instance, however, is the slightest hint given as to the theory on which these cures are obtained. A summary of the procedures discloses the fact that cancer is influenced to a degree ameliorative or curative independently of the source of the ray or quality of ray employed in its treatment. To say that any medium cures cancer without stating why it does so is the purest form of empiricsm, permissible perhaps from the fact that nearly all of our knowledge of therapeutics is empirical, a blind study, and open to question and doubt. Let us, if we wish to treat cancer, first start with a theory, any theory, as to its cause, then on this theory base the treatment, rather than begin with a treatment, any treatment, and then theorize as to the cause.

In the MEDICAL RECORD, September 1, 1917, the writer in an article entitled "An Hypothesis on the Physicochemical Nature of Cancer" gave reasons for attributing the cause of cancer to an excess of sodium chloride in the tissues of the body; ingestion taking place through the common practice of using table salt to excess with the food. The salient points of the article are the following:

That cancer is not a communicable disease and cannot be produced either by bacteria, parasites, or traumatic influences.

That it is a disease of civilization and is not found in savage races.

That the only difference in the natural foods of civilized or savage human beings lies in the proportion of sodium chloride which preponderates in the food of the former.

That before the production of salt, in the quantity now manufactured, cancer was practically a rare disease, and that with the increase in the consumption of salt cancer has proportionately become prevalent.

That the presence of salt in the animal economy is probably necessary to the function of cell proliferation and reproduction of the species.

That cell proliferation can be artificially produced and maintained by a suitable salt solution.

That cancer is 50 per cent. more frequent in the female than in the male.

That cancer is not a distinct type of tumor but merely a phase of any type of tumor.

That cancer does not begin as a malignant growth but as a simple benign tumor, subsequently passing into a stage of malignancy.

That there must exist an idiosyncrasy to salt in those persons who develop cancer.

That it is not possible to transmit cancer through hereditary influences, but that it is possible to transmit to the offspring an idiosyncrasy to salt which may have been possessed by the parents or parent.

That the difference between cancer and sarcoma is merely one of rapidity of cell destruction, as shown by the fact that sarcoma may intermingle with cancer, and the latter change into the former.

That the stimulus to cell degeneration must come from the plasma and be of a chemical nature, this chemical being sodium chloride.

That the property of the cytoplasm of the cell to create new chemicals is the factor in causing the cell to liquefy, and that this condition takes place at some point after the nucleus has divided independently of the cytoplasm.

That if cancer was a local manifestation, operation for the removal of the tumor would negative the recurrence of the disease.

That cancer is a constitutional disease and is dependent upon the chemical constitution of the blood.

That cancer attacks, to a greater degree, those organs having a large blood supply.

That cancer being engendered through the process of proliferation, those organs in which this process is naturally more highly developed are more readily affected by the disease.

That an idiosyncrasy to salt may disappear and that a regression of the tumor or cure may be due to this phenomenon.

That a cell cannot become cancerous through an independent act of its own, but must receive the stimulus to do so from the chemical constitution of the plasma, an agent of which is sodium chloride.

This article was followed by another on May 4, 1918, entitled, "A Plea for the Use of Potassium Nitrate in Cancer," the main features being the following, in which the chemical facts are beyond dispute:

Of the two elements potassium and sodium, the former is an ingredient of the cell to a greater degree than is the latter, which is found in greater abundance in the fluids of the body. The proper equalization of these two elements in the cell constitutes health. Their displacement is interchangeable. An excess of sodium chloride displaces the potassium element from the cell, and an excess of potassium nitrate would likewise lower the percentage of the sodium content of the cell. Therefore, according to the principle of maximum work in thermochemistry, which was deonstrated years ago, whenever chemical reactions are possible, as the result of the admixture of various chemical reagents, the reaction which takes precedence over all the others is that which leads to the greatest development of heat; or, in other words, the particular chemical compound will be formed first whose so-called "heat of chemical formation" is highest; and that compound will also be the most stable, or the most difficult to decompose or displace. When nitrate of potassium, composed of potash and nitric acid ions, enters the plasma of the blood, which always contains chloride of sodium, it is possible for a double decomposition to take place, by which potassium chloride and sodium nitrate are formed. Now, it so happens that the heat of formation of potassium chloride is higher than that of sodium chloride, except chloride of lithium (which is only about 1 per cent. higher, and is of no special interest in the present connection because it is not a natural constituent of blood or tissue); consequently, according to the established recognized principles of thermochemistry, not only will there be a tendency to the formation of chloride of potassium (by virtue of the principle of the tendency to maximum heat development just mentioned) but this salt will be a more stable constituent of the blood or of any of the fluids or tissues of the body than chloride of sodium.

At the same time that chloride of potassium is formed by the union of the potassium ions with the

chloride ions of the chloride of sodium present in the fluids of the body, the nitric acid ions, let loose or released from the potassium nitrate, will combine with the sodium ions of the chloride of sodium, forming nitrate of sodium. This substance can pass out of the cell tissue into the blood and take part in other chemical reactions in which nitrogen plays an essential role.

An interesting circumstance in connection with the exchange of ions taking place between chloride of sodium and nitrate of potassium is that the sum of the heats of formation of the two end-products remains substantially the same as the sum of the heats of formation of the two initial products. This means that very little energy needs to be supplied from the blood, or from sources of physical or chemical energies of the body, in order to effect the double reaction just mentioned.

Can the question be properly raised, "Is cancer a distinct entity?" In the light which pathology has thrown upon the different phases of inflammation, might cancer be nothing else than an exaggerated phase of an original inflammation, possessing no other characteristics than the peculiarity of the presence of atypical cells in the inflamed tissues? What is there to lead one to believe otherwise? Does not cancer start with an inflammation, and has anyone ever seen a cancer in which inflammation was not present? The mere fact that cell division is interfered with, in the process of an inflammation, cannot make that condition a distinct and separate pathological state while the original cause of the inflammation still exists. It seems not impertinent to ask why cancers do not develop in uninflamed tissues, but are prone to develop in old inflammation. It seems to the writer that without inflammation there can be no cancer. (In this case the deduction is that cancer is an inflamation of a malignant type.)

Cancer cells are composed of the same type of cells as those normally existing in the body, and are derived from the latter by a proliferation of preexisting cells. No appreciable advantage is gained by a knowledge of the particular type of cell which has assumed a cancerous character; the existence of metaplasia is often recognized; nor can a degree of malignancy be determined by the character of the cells or their types. The malignancy must be due to some particular agent existing in the cell whose presence is objectionable and from which the cell endeavors to rid itself. And for our belief that sodium is that agent under suspicion, we have the following reasons:

When a solution of sodium chloride is ingested it is split up into sodium and chlorine; the sodium being oxidized and the chlorine going to form the gastric juice. When an excess of sodium is present oxidization becomes incomplete and a certain amount of sodium crowds out the potassium element from the cell. It must be borne in mind that potassium is the proper element of the cell and not the sodium. It therefore becomes quite logical on the part of the cell to expel a substance irritating to its well being. This then is the first start of a local inflammation. Inflammations may differ in their etiology, but from whatever source this condition might arise the fundamental principles of inflammation are invariably present. In this instance the type of inflammation under consideration which might be correctly termed "malignant inflammation" or cancer, as you wish it, will be looked upon as being caused by the presence of sodium in the cell. Sodium is a soft, white, alkaline metallic element, is univalent, and has a strong affinity for oxygen. It is quickly consumed when exposed to air, hence in the tissues of the body it is readily oxidized in the presence of oxygen. Heat and light are but different forms of motion. Sodium is oxidized in the presence of either of these forces. Does it not seem quite plausible, if with three different forms of motion (radium, *x*-ray, actinic ray), exact conditions are brought about in an area of malignant tissue, that the curative property of such agents cannot be due to their intrinsic value, but must be attributed to their power of removing an extraneous substance whose presence gives rise to the manifestation of inflammation, or cancer?

The administration of potassium nitrate in cancer is therefore based upon logical ground and sound reasoning, from the fact that this salt displaces the excess of sodium from the inflamed cell and hastens regeneration of the tissue. Likewise the application of radium, *x*-ray or actinic ray to an inflamed area, or cancer, is also justifiable, not because experience has shown that these rays are curative, but because we know why they cure, and that the cure is brought about by their power to oxidize the sodium which the cell is incapable of removing by its own efforts.

There is a peculiar analogy between the therapeutic value of potassium nitrate and radium, *x*-ray or actinic ray in cancer. Cures have been reported by the use of any of these four agents. The writer reported two cases of cancer, one of the stomach and one of the liver, cured by the administration of a solution of this salt. The dose was 1-25 of a grain dissolved in four ounces of water and taken every four hours. A full account of his reasons for giving potassium nitrate in small doses may be found in the MEDICAL RECORD of May 4, 1918. Dr. M. J. Sittenfield reports his experience with the use of radium in the MEDICAL RECORD for March 1, 1919. Dr. Isaac Levin, in the MEDICAL RECORD for April 5, 1919, enlightens us with his knowledge of *x*-ray in cancer. And we have an instructive report by Dr. T. Howard Plank of Chicago on what he has accomplished in cancer by the use of actinic rays. Now may we not ask, if four distinct agents are capable of bringing about a cure in one particular type of disease, what can there be present in this disease on which these four agents have similar action? In the opinion of the writer the thing present is sodium. Therefore, the cause of cancer is the presence of an excess of sodium in the cell, and the cure of cancer is dependent upon the removal of this irritant, irrespective of the means employed. Logically, then, it can be stated that the cause and cure of cancer have been discovered, and until what has been stated here is disproved, a belief to this effect must remain in the mind of the writer.

It is the firm belief of the writer that oxidization plays an important part, if not the entire rôle, in the cure of cancer by rays. Investigators with the *x*-ray, for example, have been struck by the fact that the rays have a destructive action on

cancerous tissue and not on the less malignant mass surrounding it. And as stated by Dr. Levin (MEDICAL RECORD, April 5, 1919, page 557), "The difference in the mass of tumor offers the only explanation of the fact that the deeper part of the sigmoid tumor, which was hardly more than 5 cm. from the skin, was not influenced by the rays, while at the same time tumor islands in the peritoneal nodules, some of which were situated at many times a greater distance from the skin, were either destroyed or deeply influenced by the rays."

The explanation of this would seem to be due to the fact that the peritoneal nodules were more cancerous than the tissue constituting the sigmoid tumor, a more advanced degree of cancer presumably, and that the cancer tissue of the nodules contained some element in greater proportion than the surrounding tissue. It is permissible to conjecture that the peritoneal nodules, although much further from the rays than the sigmoid tumor, were acted upon because they contained something which the rays were capable of removing. And it might be conjectured that this something was sodium, an element capable of being oxidized or burned up. Hence after the sodium had been oxidized the nodules were destroyed. It is logical to assume then that malignancy of cancerous tissue is dependent upon an element which the action of light rays, in whatever form, removes. And since sodium is rapidly influenced by oxidization and is the only adventitious substance of the cell capable of causing malignancy, might it not be reasonable to consider the phenomenon more than a mere coincidence? (The deduction that malignancy is due to sodium in the cell is in keeping with the premise of the thesis.)

The doctor also notes that the effect of the rays on every malignant tumor is to inhibit their proliferative activity. We know that irritation stimulates proliferation in cell tissue. If, therefore, in the case of cancer, the irritation, which is due to the presence of sodium, be removed through the oxidizing power of the ray on the sodium, or through the physical property of the sodium to be oxidized by light or heat, it is quite within reason to expect that proliferation should be inhibited. And further on the doctor remarks that "Radiated and non-radiated carcinoma tissue may have the same microscopic appearance, and still the former tissue is sterilized and may have lost to a great extent its power of proliferation and consequently its clinical malignancy."

This does not seem phenomenal, from the fact that the quantity of sodium in a cell, or cells, sufficient to give rise to malignancy could not possibly be detected by the microscope, considering the limited field in which this instrument can be employed. The better and more appropriate instrument for the detection of any physical change in a cancer cell after sterilization by radiation would be the spectroscope. For the sodium spectrum should be markedly pronounced in non-radiated tissue, and proportionately dimmed after the tissue had been subjected to radiation. The writer is now working on this problem.

It should be realized that the spectroscopic evidence affords proof of the presence, but not necessarily of the absence of substances; *e.g.* we might interpret the absence of the dark lines of sodium to mean that either there is no sodium present or if present it is not in a state capable of absorbing the characteristic light.

The general characteristics depending on the relative position of lines proclaim the chemical origin of the spectra, the variations may indicate the physical conditions of the substance emitting the spectra.

In the Bunsen flame the yellow lines of sodium are seen to widen whenever additional salt is added, and to become narrow when the vapor of the salt is reduced.

However, the use of the spectroscope for the detection of an element suspected of being the cause of cancer requires special technical skill, which is of a quality not possessed by the writer. In fact, investigation with this instrument belongs more properly to the physicist and the astronomer. Although researches in cancer are being made by the medical profession, it would not seem inappropriate if, in a problem possessing such vast importance to the entire human race, professions other than that of medicine should contribute their aid and scientific knowledge.

It is indeed most singular that from whatever angle the subject of the cause and cure of cancer be viewed, the presence of sodium manifests itself. There is no argument against it, and every phenomenon seen in cancer, be it constructive or destructive, reveals with strong suspicion the presence or absence of this element. And the experiences of four men, working in the same channel with four distinct therapeutic agents, and all four declaring similar results, furnishes such an overwhelming abundance of circumstantial evidence that sodium stands irrevocably convicted. Indeed, these investigators by their published reports have unconsciously, yet materially, strengthened the theory of the writer that sodium is the cause of cancer.

452 FIFTH AVENUE.

TREATMENT OF PNEUMONIA.

BY LEO KIRBY, M.D., L.M.S.S.A. (Lond.)

NOTTINGHAM, ENGLAND.

IT was not my good fortune, while attempting the practice of medicine in New York, to see personally much of pneumonia, barring children under three. But even beyond the appalling statistics of Osler—about two hundred and thirty-odd fatalities out of six hundred and fifty—to me, as an outsider, it seemed more nearly an hundred per cent. Almost every one whom I heard of seemed to die. It was almost a matter of special comment if one heard of one's recovery therefrom. Since my expatriation, a matter of ten years, thanks to the repeated spells of influenza I have made up for lost time. And not alone that, but my experience has well covered the map of England and a bit of Wales. As a result of this I am prepared to say that pneumonia in an individual not too old (say not past 60) and not complicated by precedent organic disease, and itself not unduly septic, should be attended by practically invariable recovery. This statement will most probably seem exaggerated to many readers. But following the plan of treatment I evolved during a journey across the American continent in 1905, in the many cases I have had here in private and in hospital work, I have lost, all told, but three

—one a man of seventy-six, with advanced arterial atheroma; one a man of fifty, with pronounced emphysema; and the third an Indian, with advanced tuberculosis.

Not being of a statistical mind, I unfortunately cannot give this article the scientific turn that many would demand, so I shall be obliged to ask my readers to accept its empirical presentation, one much more conformable to mine own self. But this I will say: that if the methods I outline are fairly well followed there should be practically one hundred per cent. of recoveries. Of course, the personal factor of the physician counts for much. But a New York practitioner who followed my methods cured every case.

Thus, in evolving what for want of a better name I may be allowed to term my specific treatment of pneumonia (and indeed of influenza and practically all other catarrhal fevers), I had resort to an analysis of their several and respective indications. But in this there was a deliberate avoidance of "allopathy," *i. e.* the treatment of symptomatic manifestations! About the only exception I make is in case of the severe, sharp, and nigh maddening pain in the congestive stage. Here I have employed a hypodermic injection (preferably over the site of pain) of gr. ¼ of morphine and gr. 1/150 of atropine, both usually of the sulphate salts. This has served invariably as an analgesic, the atropine serving to deepen and prolong the morphine effect, and reliably protecting from the morphine depression in the respiratory centers and both effecting a deep sedation of the cardiac muscles and nerves, with slowing and toning of the heart's action. It also exercises an unquestioned inhibition on the pronounced tendency to acute mania in the early stages of pneumonia; it also exerts a powerful counter effect on the depression so often present in both pneumonia and influenza. Apart from these, the writer has, thus far, never had occasion to repeat this initial dose.

The next step was the choice of a drug to overcome and to prevent the definitely weakening tendency upon the vasomotor centers and nerves of the pneumonic and grippal toxins. In the very first rank here belongs digitalis. This must be given in large and very frequently repeated doses: thus ♏xv of the 10 per cent. tincture, associated with other drugs, and repeated every two hours between 8 A. M. and midnight, and every four hours between midnight and 8 A. M., if the patient be awake. Initially, I give a large and well guarded dose of calomel, following the Leaming method, of ten to fifteen grains. In it, in such dose, we have an almost ideal intestinal antiseptic. My recipe, therefore, is as follows: Calomel *purissimum* (ether washed) combined with twice the weight of sodium bicarbonate (c. p.) and 1 to 1½ grains of extract of hyoscyamus. Without an absolutely reliable preparation of this latter I should be rather chary of any such large calomel dose. Indeed, in such a case I give only a half grain of calomel night and morning for two days. When the large dose of calomel is given I defer for one, or even two, hours all further medication. When unable to obtain an absolutely reliable preparation of hyoscyamus I have used only the smaller doses of calomel. The following was my first formula:

℞ Tr. digitalis (10 p. c.).....ʒss (15 c.c.)
Liq. ammon. acet. (conc.)....ʒi (30 c.c.)
Aquæ q. s. ad.....ʒviii (240 c.c.)

Of this, one-half ounce was given in soda water every two hours during the day and every four hours at night, if the patient were awake. Gradually, during the past nine years, this has been modified by the addition of oxymel of squill and glycerite of pepsine, of each ʒi (30 c.c.).

In the ammonium acetate and the squill a series of indications are met: a general stimulation, a persistent general and well-borne diaphoresis and diuresis, eliminating the toxins; in the bronchi a thinning of the viscid pneumonic sputum, thus aiding the expulsion of the septic contents of the bronchi. Thus given, in sufficient dose, the formula determines fully the two important indications of stimulation and elimination, which in all acute general febrile maladies are practically the main ones. The oxymel not only carries this out but further renders the mixture much more palatable and far better borne. It is recently that I have added from half to an ounce of the British official glycerinum pepticum, but the thickly furred and often rather foul pneumonic tongue is obdurate to its action, at least until crisis or lyses.

A further very important measure is the high saline injection, at least a quart twice daily at not less than 115° F. But here, outside of hospital cases, this measure is practically unavailable.

When the large doses of digitalis (♏xv of the 10 per cent. tincture every two hours in the day and four hours at night) fail to maintain a proper pulse tension it is expedient to supplement it with digitalone, gr. 1/10, or digitalin, 1/100 gr., hypodermically from two to five times daily. The digitalone is far and away the better. In the case of three girls in the wards of a poor law infirmary, where the digitalis was of poor quality, their lives were unquestionably saved by the hypodermic administration of digitalin day and night. When edema of the lungs occurs, as happened recently on the fifth day in a case of disseminated sclerosis, with the entire right lung consolidated, ♏vij of the 1/1000 adrenalin solution should be immediately given hypodermically, followed by digitalone, also hypodermically. This will nearly always bring immediate relief. The adrenalin should be repeated p. r. n. if edema recurs; otherwise, the digitalone only, but then every four hours. The above mentioned case was carried to crisis on the seventh day. In this case the pneumonia as evinced by the sputum was septic in type, and the pulmonary edema was almost undoubtedly due to a septic toxemia of the respiratory and vasomotor centers in the medulla.

In the matter of food, on the one hand what we call nature has its work here cut out for itself. So it is thoroughly expedient to eliminate all demands upon it to modify and assimilate the ingesta. Thus, contrary to general practice, milk should not be given save as a medium for very strong coffee or tea, preferably the former, of which the patient cannot get too much. The ideal food is grape juice, either alone or with plain soda. This is amply nutritious, cooling, and refreshing to the patient, and very definitely antiseptic in its intestinal action, and also admirable in its action on the hepatic cells.

The tolerance developed for digitalis in these combinations is simply astonishing. Thus, recently, in a hospital, a boy of two, of a very rachitic type, was given five minims of the official British tincture two-hourly for two days and then three-hourly for another day, and even this was supplemented by digitalin 1/200 gr., twice daily for two days. Here the temperatures ranged from 104° F to 106° F.; pulse, 160 to 180; respirations, 35 to 48. The entire right lung was consolidated. Recovery occurred by lysis. Unhappily, our efforts were partly nullified by subfebrile temperatures, which were found to be due to a right basilar tuberculosis. This, however, at the time of our parting company, seemed much better.

Another instructive case was in the person of a highly neurasthenic, very thin Swindon boilermaker of fifty. He began on Christmas, 1917, with an influenzal right basilar lesion, which in two days had invaded the entire right lung and the entire lower lobe of the left. Thus the respiratory capacity was limited to the left upper lobe. Not a very promising case! So grave did his case seem to his comrades that they actually, in anticipation of his death, had appointed a committee for his funeral. This, however, was, despite all, not my expectation. After a hard fight indeed lysis occurred about the fourteenth day. Even then convalescence was a slow matter, and was complicated by a series of rheumatic phenomena. Finally, after three months, he returned to work.

It is now my firm conviction that the average case of pneumonia, treated as I have outlined, will practically invariably recover.

In several cases with the most unequivocal signs of the congestive stage, especially diffuse inspiratory crepitation posteriorly, with much impaired resonance, the process has been aborted within twenty-four hours. Temperatures ranging from 103° to 106° F. have fallen to normal, and all physical signs have disappeared.

The only form of pneumonia in which I feel special anxiety as to the result is that following measles. Fortunately, I have had but little experience with that form, but such as I have had has not been encouraging.

27 Brierley Street.

THE INTRAVENOUS USE OF IRON AND ARSENIC IN OVER 100 CASES.

By LOUIS STERN, M.D.,

NEW YORK.

There have appeared during the last decade in American medical journals several articles dealing with the intravenous method of drug administration. The majority of such articles were abstracts from foreign publications. I believe that the attitude of American physicians toward this most promising field of therapeutics is growing more favorable. I also believe that there exists in the minds of many American medical men a fear of introducing any foreign substance directly into the blood stream. This is natural, in view of what used to be taught in medical schools, also on account of the published reports of shock or unpleasant reactions that have occurred from the use of salvarsan.

Clinicians have reported upon intravenous therapy in emergency cases at the hospital. But such evidence has not been particularly encouraging, especially in view of the fact that large volumes of the solution injected—from 300 c.c. to 700 c.c.—were held to be necessary. As a matter of fact, I can positively state that the giving of such large amounts together with faulty technique in preparing the solutions were responsible for unpleasant results.

The writer, as a result of his experience during the last three years with the intravenous method of drug administration, can declare absolutely that it has been demonstrated to be not only practical, but as nearly ideal as we can hope to secure. There is no question that in overcoming all difficulties of absorption by placing the remedy directly in the blood stream, we have reached the ideal method. I use the word "ideal" because within the limited field of my own experience, the results obtained fully warrant the term.

I have had no experience with extemporaneous solutions. The remedies I have used were made by a New York laboratory, and regarding them I can say that the general practitioner can safely and practically use them intravenously, either in his office or at the bedside.

The solutions are furnished in sterilized glass ampoules, each containing from 5 to 20 c.c. of solution, with an exact statement of the contents on the label. The technique of administration is simple. The patient's arm is exposed and the prominent veins about the elbow joint are made to stand out by the use of constriction in the form of the cuff of a blood pressure apparatus. The median cephalic vein is usually selected. The skin is thoroughly cleansed with alcohol. The ampoule is broken at the neck and its solution drawn into an all-glass syringe, to which is attached a 23 gauge, ¾ of an inch, hypodermic needle with a sharp point.

The patient's arm is supported on the side arm of an operating table, the thumb and forefinger are placed on either side of the vein to steady it and keep it from moving, and the needle is introduced into the vein. The use of the fine needle instead of the dull, brutal intramuscular one, is a big improvement. The injection has to be given slowly, no matter how hard the piston of the syringe is pressed. After the needle has entered the vein, blood comes back into the solution, indicating that the needle is safely in the blood-vessel. Rarely is it necessary to withdraw the piston a little, in order to make sure of this. As soon as the operator is satisfied that the needle is in the blood stream, pressure is released and the injection is given.

After repeatedly timing myself, I find that it rarely requires more than five to six minutes from the time of exposing the arm to finish the injection. After the syringe has been emptied, the needle is pulled out, and the puncture is pressed upon with a pledget of cotton, which has been saturated with tincture of iodine and held there for about one-half minute. I believe that the truly therapeutic properties of many of our common remedies have been only slightly developed, and that by the intravenous method it will be possible to learn their exact value in pathological conditions.

I have used sodium iodide and salicylate, hexamethylenamine, and other remedies by this method. My interest has been centered, however, upon the use of iron and arsenic intravenously. For years, I was in the habit of using various combinations of iron and arsenic intramuscularly, but since using these remedies intravenously I have been able to make a new estimate as to their value. The solution employed contains 64 milligrams (1 grain) of iron cacodylate. Injections are given at intervals of from four to five days.

In every single case, anemia was promptly corrected. Two cases of incipient tuberculosis responded well and the progress of the infection was absolutely arrested. A number of neurasthenic cases, in one of which there was a decided psychosis, reacted wonderfully.

In three cases of women with hysterical thyroid disturbance, there was a prompt response with diminished symptoms after each injection. Six injections were given in all.

Another case was that of a man who had returned from the tropics with chronic diarrhea and severe anemia. Bowel movements were corrected and the general improvement was remarkable after four injections.

In four cases of chlorosis with extremely low hemoglobin index, the index was brought to 90 within 40 days by the use of eight injections in each case.

The results obtained in postoperative anemia, and in the anemia following pneumonia and other acute infections, indicate that it is an ideal method of hastening convalescence.

In a theatrical man, with failing voice and severe neurasthenia, a remarkable recovery was obtained, which could not be attributed to local treatment.

I want to emphasize very strongly one fact that has been brought out by my experience with intravenous therapy, which is, that many symptoms that are regarded as reflexes from the central nervous system, disappear as soon as the blood content is improved. It is impossible after such an experience not to conclude that an unbalanced blood content is responsible for many reflex nervous symptoms, for which it is impossible to find any lesion or infection.

The writer wishes to emphasize that the general practitioner possesses ample skill required to introduce the hypodermic needle into the vein and hold it there for a minute or more, while making the injection.

Intravenous therapy can be carried out as an office routine. I have never had an injection followed by what could be called an alarming reaction. There are, of course, "needle shy" patients who perspire and rarely feel faint, or actually do faint. This is purely psychic. In rare instances a little nausea is complained of after the first injection of iron and arsenic. I have never encountered any evidence of reaction in the form of chills, depression, or shock.

When it is borne in mind how many times digestive disturbances and other shortcomings of the oral method occur, and how frequently abscesses occur, and hyperemia and pain follow the intramuscular method, there is no question that the intravenous method is more scientific, more direct, safer, and more efficient. With proper technique, there is no leakage or infiltration. The patient feels no pain, except the prick of the needle as it goes through the skin.

My experience with this method of using iron and arsenic was so satisfactory that I determined to ascertain the exact change which took place in the blood, using a Leitz blood counting apparatus and the Tallquist color test. The results are given below:

	Red Cell Count and Hemoglobin.	
Male, 37. Vertigo, mental confusion and depression, chills and fever. Skin pale, tenderness over spleen. Anemia. Iron and arsenic intravenously every fourth day for seven doses. Rapid improvement in general health.	Oct. 2 3,500,000 70	Nov. 10 4,800,000 90
Male, 28. Very slow recovery from pneumonia; depressed, weak, cachectic appearance; profound anemia. Iron and arsenic every fourth day, six doses. Patient picked up very rapidly.	Oct. 10 3,300,000 70	Nov. 10 4,750,000 90
Female, 33. Anemia following removal of appendix, a severe pus case. Convalescent. Very decided improvement noticeable after the first injection.	Sept. 18 3,250,000 70	Oct. 22 4,300,000 100
Male, 45. Overworked business man, complains of gastric disturbances; lost weight; excitable, irritable; neurasthenic; anemic appearance.	Nov. 6 3,750,000 70	Dec. 10 4,750,000 90
Female, 28. History of grippe previous spring. Summer vacation failed to establish normal health, weak, easily tired out; neurasthenic, anemic. Could find no lesion or sign of infection. Iron and arsenic intravenously every fifth day, six doses.	Sept. 15 3,000,000 70	Oct. 16 4,200,000 90
Male, 30. Referred to me by out-of-town physician for treatment as incipient tuberculosis. Temperature 99° to 102°; loss of weight, anemia evident. Iron and arsenic every fifth day for eight injections. Temperature fluctuations kept below 99.5° after third injection. Rapid improvement and increase of ten pounds in weight.	Sept. 20 3,250,000 70	Oct. 30 4,500,000 90
Male, 32. Complains of loss of strength, appetite, and sexual desire; neurasthenic, anemia evident. Iron and arsenic intravenously every sixth day for six injections. Rapid gain in weight, subjective and objective symptoms very rapidly improved.	Oct. 18 3,700,000 70	Nov. 20 4,500,000 100
Girl, 16. Vertigo, headache, scanty menses, yellow skin, anemia; typical chlorosis. Iron and arsenic intravenously every fifth day for seven doses. Most rapid improvement. Weight increased eight pounds.	Oct. 12 3,750,000 60	Nov. 15 4,250,000 90
Female, 30. Hysterical, neurasthenic, hyperthyroid symptoms; weight, 113 pounds. Six injections iron and arsenic at five-day intervals caused very rapid improvement of symptoms. Weight, 122 pounds.	Oct. 14 3,250,000 70	Nov. 15 4,250,000 100
Man, 39. Returned from tropics, had been suffering ten months with chronic diarrhea. Blood test shows no malaria. Acute attack preceded the chronic condition. Administered fifteen grains quinine bisulphite enema thrice a week for two weeks. Iron and arsenic intravenously every fifth day for six doses. Bowel movements subsided to one a day after third injection. General condition immediately improved.	Oct. 15 3,000,000 60	Nov. 20 4,500,000 90

116 West Forty-fifth Street.

Death of Dr. Barnsby of Tours.—Despite his English sounding name, Henry Barnsby was a well-known French surgeon who at the outbreak of the war was in charge of an ambulance and was associated from first to last with his brother Pierre. He ended by becoming chief surgeon of a sector. Early in January last he contracted influenza, which led to a cervical phlegmon. Death occurred in a few minutes from perforation of the carotid.—*La Presse Médicale.*

Professor Hartman on Cancer.—The views expressed are really those of Lumière who claims that all of the usually advanced hypotheses fail to throw any light on the nature of cancer. Only the stimulation of a parasite within the cell can cause the latter to behave in the atypical fashion of the cancer cell. Naturally we do not expect this view to be advanced without demonstrations and the author has continued the labors of Borrel in this field. Many series of experiments need to be carried out, and the labor is attended with extraordinary difficulty.—*La Presse Médicale.*

Medical and Surgical Lessons of the War.

A GENERAL CONSIDERATION OF WOUNDS OF THE HEAD IN THE WAR.

By EDWARD ARCHIBALD, M.D.,
MONTREAL, CANADA.
FORMERLY MAJOR, C.A.M.C.

It can, perhaps, hardly be said that the war's experience has advanced our general knowledge of craniocerebral wounds in so great a degree as it has along some other lines of medical work; yet we have not done so badly on the whole. We have certainly got, to mention only a few instances, a clearer comprehension of the effects of high velocity missiles, especially of high explosive fragments; we have learned some new things in symptomatology, such as the longitudinal sinus syndrome so clearly established by Holmes and Sargent (to mention only one thing); we have definitely worked out a better operation for penetrating wounds than we had before; and we have learned a good deal about the prognosis as to late results, particularly with regard to epilepsy, insanity, abscess, and other things. The purpose of the present article goes no further than to present the subject of head injuries in a very general way. Exigencies of space will preclude much detail.

Missiles in the present war may be said roughly to fall into three categories: the pointed bullet, the round shrapnel bullet, and the fragment of a high explosive shell. The lesions caused by any of these three vary greatly according to velocity at the moment of impact. The cardinal point concerning the relation which the velocity of a missile bears to the amount of damage which it causes (one which is not sufficiently appreciated), is that a projectile, possessed of great velocity, gives out force or violence not only in the direct line of its path, but also at right angles to that path. There are many examples of this in the literature. For instance, Sir Anthony Bowlby[1] refers to a specimen of a kidney shown by the pathologist, Stokes, at a British Casualty Clearing Station, in which, a rifle bullet having passed through the lower pole of the kidney, it was impossible, in microscopical section taken from the upper pole, to determine even the general character of the tissue or to recognize that it was kidney. The writer saw this specimen soon after it was prepared. Two other examples of this fact, even more striking possibly than that just mentioned, came under the writer's observation. In one a big fragment of high explosive had swept away most of the frontal bone and the tips of the prefrontal lobes of both sides. In spite of the vast wound the patient did fairly well for about two weeks, when, of a sudden, there occurred a large escape of cerebrospinal fluid on the right side, followed by death in three days. The autopsy showed a necrosis of the frontal lobe on each side, extending back right to the anterior horn of the lateral ventricle. With degeneration of the necrotic tissue, the ventricle was ultimately opened on the one side, and almost opened on the other. In another instance, a tangential gutter wound of the vertex, cutting through the dura and the surface of the cortex, caused a necrosis of brain tissue which extended vertically downward at right angles to the path of the missile, into the lateral ventricle and even through it, causing necrosis of the ventricular surface of the optic thalamus. It must, therefore, be kept clearly in view that a missile passing through the brain with high velocity does not merely drill a hole but causes also a broad path of destruction. The converse is naturally true whereby the lower the velocity the less extensive is the necrosis of tissue outside of its immediate track.

It is thus seen that great velocity is equivalent to great radiating energy. And if this radiation of energy is developed inside a bony case, such as the skull, filled with semi-fluid material (the brain) the destructive effect may be enormous, if the velocity at the moment of impact is enormous. Thus we may get varying degrees of damage, from maximum to minimum, as follows:

First, explosion. In this the vertex is fissured in all directions or is even completely blown off; the scalp and dura are widely torn open by the bursting effect; a large part of the brain is disorganized, or the brain in rare instances is even projected, almost entire, outside the skull. Such an extreme effect is found only at very close range, usually point blank.

Second, perforation. With a lower velocity the wound of entrance is usually small and that of exit large. The path of the missile may be from one side to the other, or tangential with the two wounds on the same side of the skull, forming what is often called a seton wound. Such occur, naturally, in the parietal region chiefly. Bone fragments from the inner table are likely to be driven, or "showered," into the brain substance to an equal degree in both types of injury, and often to a depth of two inches or more; but infection is more likely to be carried in by the direct perforating missiles.

Third, with still lower velocity, penetration only, the missile lodging in the brain. Occasionally the missile may traverse the brain completely and ricochet once or even twice.

Fourth, contusion or fracture of the external table, with or without fracture of the inner table. The dura is sometimes torn by a spicule, sometimes remains intact. Such injuries are frequently produced by tangential or gutter wounds, but may also be caused by a low velocity missile which strikes directly and bounces off. In either case there may be present a quite considerable bruising of the brain immediately subjacent, with or without cortical hemorrhage. This rarely extends more than half an inch into the brain substance, although I have seen it go as far as an inch, forming what looks like a hemorrhagic infarct.

Fifth, the scalp alone is injured, the bone being intact. It is noteworthy that even with these superficial wounds, and even when the pericranium has not been torn, there may be fissured or even slightly depressed fractures of the underlying bone, and superficial bruising of the brain itself. Such effects are certainly due to high velocity glancing wounds, giving off great energy, or violence, at right angles to their path.

Pathological Lesions.—(a) The Scalp: The lesions vary according to the type of missile, from the small abrasion, or penetration of tiny shell frag-

ments, to vast lacerated and dirty wounds caused by glancing, high velocity bullets or pieces of high explosive. The tiny wounds frequently remain sterile, yet asepsis can never be counted on, and practically all wounds must be excised. Frequently one finds an abscess under the pericranium, around a small fragment, while the superficial wound seems healthy and is covered by a scab.

(*b*) The Skull: These have been already partly indicated. The principles obtaining in the surgery of civil life remain valid in war surgery. Blunt, diffuse violence is apt to cause bursting fractures, with fissures, while circumscribed violence produces depressed fractures, with or without penetration of the dura. In war wounds the former mechanism is rarely seen unmixed. The bursting effect, with the production of radiating fissures, is, however, very often provided, both in penetrating and in tangential wounds, through the radiation of energy at right angles to the path of a high velocity missile, whereas a low velocity missile gives a clean-cut depressed fracture or a drill-hole perforation of the skull without fissures. The usual inbending of the external table and splintering of the internal table corresponds with that seen in civil life upon the application of localized violence. When the missile penetrates the skull it usually carries with it a number of small fragments from both tables. I have picked out as many as eleven of these from the track in the brain substance, as deep as six or seven centimeters. It is not so frequent an event as one might expect to find pieces of the service cap carried in. When the skull is perforated, the wound of exit is often, though not always, larger than the wound of entrance. After the introduction of the steel helmet, early in 1916, pieces of the helmet were occasionally carried into the brain along with bone fragments, but this was comparatively rare. The helmet was more apt either to be perforated clean, by direct hit, or guttered, with inturned shelving edges, by tangential hits, and consequently the wounds made by the breaking of the helmet were usually lacerated and superficial.

(*c*) The Meninges: The dura is rarely opened to any greater extent than the skull. Ordinarily it is found to coincide with the margins of the bone opening and sometimes it is smaller. The same may be said of the pia arachnoid. The amount of bleeding from the latter is usually trifling, unless a sinus happens to be torn. As a result of the rapid swelling of the injured brain, with early herniation into the bone opening, the pia arachnoid is quickly pressed up against the dura, around the wound opening, and seals off the general meningeal space, so that a primary meningitis is nearly always prevented.

(*d*) The Brain: The pathology of the brain injury has already been partly indicated. Whether from the radiation of lateral energy from high velocity missiles or from the heat of the missile, or from both, it is usual to find that the area of destruction of brain substance is decidedly wider than the actual track of the projectile. What one ordinarily sees, after removing the contused scalp edges, is a hole in the skull plugged by a small hernia of bruised and disorganized brain tissue, in the center of which is a track filled with brain mush, indicating the path of the missile. It is perfectly easy to recognize the direction and the depth of this channel by the feel. For this purpose the finger is too gross an instrument, nor is it necessary; for the track can be quite well recognized with a small rubber catheter, or a sinus forceps, or a probe—any one of which slips much more easily through the brain mush than through healthy brain tissue. The transition from one to the other is quite clear from the differing sense of resistance, and, with a little practice, one can be confident of not poking into uninjured brain. Along the track there are usually to be felt small splinters of bone, which can be withdrawn by a sinus forceps without trouble.

The degree of reaction to the trauma on the part of the adjacent brain varies with the degree of violence and of infection, if that occurs. In the neighborhood of the track there are produced capillary hemorrhages and edema, which often, in the course of a very few hours, bring about herniation and extrusion of part of the pulped tissue lying in the wound track. In addition, when the impact has been severe, there can be found at autopsy the capillary hemorrhages of general concussion scattered throughout the brain. Frée bleeding in the brain tissue is rare. Hardly ever is the amount of brain swelling so great as to cause cerebral compression sufficient to threaten life. Those who die on the field die from the severest grades of concussion, with overwhelming inhibition of the medullary centers. Those who succumb in the Casualty Clearing Stations, after the first twenty-four hours, do so from advancing compression, which is rare; or from meningitis, which is not so rare; or from spreading encephalitis; and occasionally from the shock of ill-judged operations, with carelessness as to loss of blood during the operation. And those who die at the Base, from the first week on, are most frequently the victims of slowly progressive infection in the brain substance; sometimes of a late meningitis, which is often metastatic and hematogenous and is not often a spreading infection from the site of the wound. Save, indeed, when the ventricles have been opened by the missile, and then death is the rule, nearly always by infection of the cerebrospinal fluid. Not infrequently the cause of death remains unclear.

Glancing wounds, as already said, may cause, without opening the dura and even without breaking the skull, a localized contusion of the subjacent brain amounting even to necrosis, and this may be accompanied by a tear of pial vessels with considerable bleeding; so that, upon trephining, the dura is found tense, without pulsation, and bluish. On incising it one may evacuate a respectable quantity of free blood and clots and a small amount of brain mush.

The Complication of Infection.—It falls to be said, in the first place, that infection of the brain, while frequent, is decidedly less so than one would expect. Of course many of the men died in the first few days from the physiological effects of their injuries before infection had time to develop; but of the surviving cases it was rather remarkable how large a proportion could be transferred to England after two to four weeks in fairly good condition, and how infrequent, on the whole, was the development of late cerebral abscesses in England. (For

figures and further details the reader is referred to the paragraphs on late results.)

However, the bulk of the cases that died at Base, after the second week, did so from spreading infective encephalitis. The brain, in such instances, at post mortem, usually showed a small abscess, composed of degenerated and necrotic brain mush, of a varying degree of fluidity from the admixture of pus, lying along the track of the missile, and around it for a variable distance an opaque-looking, slightly grayish and edematous brain tissue, not otherwise altered.

The appearances, on gross examination, were often astonishing in their apparent insufficiency as the cause of death. Large abscesses were rare. As a matter of fact, quite a large proportion of cerebral wounds examined bacteriologically were found to be sterile. (Tissier.) The bacteria found were of the varieties isolated from wounds of other parts of the body and belonged, obviously, to the much-manured soil of the country. The *B. perfringens* of gas gangrene was occasionally met with and caused multiple gas cysts throughout the brain. Julian Grenfell, the poet, died from this variety of cerebral infection.

Cortical meningitis, spreading from the wound of entry, as a cause of death, was astonishingly rare. In a small series of some forty head wounds, with penetration of the dura, analyzed by the writer in the fall of 1915, before the helmets came in, there were found only three cases of meningitis, and none of these had spread from the cortical wound. Two appeared late as a complication of septicemia and one proceeded from an infection of the ventricles which had been perforated by a shell fragment. This last modus was indeed the common one in the causation of meningitis.

Symptomatology.—1. General Symptoms of Concussion and Compression: It is generally understood that the severity of concussion symptoms bears a direct proportion to the degree of violence, and also, though to a less extent, to the site of the lesion in the brain. Other things being equal, the closer to the medulla the more profound and dangerous is the concussion; and wounds in the frontal region are less likely to produce severe concussion symptoms than those in the middle or posterior regions. With regard to the violence of the impact, the blow imparted by a high velocity missile, whether pointed bullet or shell fragment, is a much heavier one than is the case with a round shrapnel bullet, which rarely possesses a velocity sufficient to perforate the skull and is often found embedded in the brain or even in the bone at the point of entrance. The steel helmet has undoubtedly saved a very large number of men, not only in preventing the penetration of small shell fragments or spent bullets, but also in reducing the velocity of such missiles as manage to penetrate. Men who, in the first year and a half of war, died on the field from concussion and the general explosive effects of close range projectiles, lost their lives largely because of the lack of head protection. Such cases, after the helmets came in, survived till they reached the casualty clearing station or the Base, and many of them were cured by timely operation.

The early symptoms of concussion, physiologically considered, may be set down as the result of a hyperacute anemia of the cortex on the one hand, the result of which is unconsciousness, and of the vital centers in the medulla on the other hand, the result of which is inhibition of the heart through the vagus, of breathing through the respiratory center, and of the pulse through the vasomotor center. If the concussion is sufficiently severe and there is opportunity of examining the wounded man immediately after the injury, he will be found pulseless, not breathing, and profoundly unconscious. Sometimes this condition is irrevocable, and this represents sudden death; but frequently the vital centers struggle back after the first two or three minutes, and then one finds an extremely feeble pulse, at first very slow and later running up to 80 or 100, a blood pressure registering from 50 up to 80, and a shallow, irregular respiration. It may take, in bad cases, from twelve to twenty-four hours for blood pressure to rise above 100, or for breathing to become normal. It follows from this that pure concussion of severe grade is chiefly seen by the medical officers of battalions, or in field ambulances, and to a less extent in casualty clearing stations, depending on the length of time it takes to get the wounded man back to a casualty clearing station. Those that survive the terrible effects of profound concussion usually arrive at a casualty clearing station with the symptoms of slight compression, the inhibitory or shock-like effects of concussion having passed off. Nevertheless, some are still suffering from the shock of concussion, and John Fraser[2] early called attention to the danger of operation under such conditions. No head injury should be operated on when blood pressure is below 100, breathing shallow, and pulse weak or fast.

With regard to the question of cerebral compression, it may be said that experience of head wounds in recent wars had not led us to expect that any dangerous degree of compression was to be feared, outside of a few cases; and the experience of the present war has, on the whole, confirmed this view. During the first year of the war it was a routine practice on the part of many surgeons to remove a wide circle of bone around the wound of entrance, in order, as it was said, to afford decompression. This was hardly logical, because there was never any thought of opening the dura widely at the same time, and without opening the dura the amount of decompression obtained is minimal.

As a matter of fact, the average penetrating, or even perforating, head wound in this war has not been followed by any serious degree of general brain compression, although the almost regular occurrence of hernia in the wounds of entrance and of exit, as also a slight rise of blood pressure, rarely exceeding 140 millimeters, together with, at times, a moderate slowing of the pulse, indicates the presence of *mild* compression. This is clearly due to reactionary edema and bleeding around the track of the missile in the brain. Conditions are different if a sinus is injured and a large escape of blood takes place, but such cases have been rare, either in the casualty clearing station or down at Base. In these, death would be more apt to occur on the field or in the field ambulance. In the writer's cases blood pressure records were taken and lumbar punctures, with measurements of the spinal pressure,

were done with fair regularity, and the above statements are made on the basis of this experience. Other observers, also, are fairly agreed as to the correctness of this view.

The general symptoms, those referable to the cortex as a whole and to the vital centers, varied, naturally, according to the severity of the lesion. Tangential wounds, without penetration, frequently caused unconsciousness lasting a few hours, as the mere effect of concussion; but such cases ran a favorable course as a rule.

Penetrating and perforating wounds carried a worse prognosis. The symptoms of general compression would usually disappear within three or four days with the absorption of fluid exudate, but unconsciousness might persist for much longer. Later symptoms in such cases depended chiefly upon the complication of infection. As already said, meningitis, spreading from the wound through the pia-arachnoid, was comparatively rare, but infection of the brain substance, or of the cerebrospinal fluid in the ventricles when these were perforated, was rather frequent. Under these circumstances, usually some time after the first week, and often until the third and fourth weeks, the occurrence of infection was heralded by a rapid rise of temperature together with increase in pulse. The patient who, up to that time, appeared to have a very good chance of recovery usually died in the course of a few days, showing all the symptoms of acute cerebral infection, gradual loss of consciousness, restlessness, delirium, and various paralyses. If the infection progressed from the ventricles, one saw develop the ordinary signs of a basal and spinal meningitis, with the usual stiffness of the neck, and the Kernig sign.

Many of the patients, however, escaped this fate. The brain wound remained aspetic, or slight infections were overcome, the small cerebral hernia receded, the wound in the scalp, usually left open in the early years of the war, granulated over, the original paralyses disappeared to their residual level, and the late results were, on the whole, rather good.

In a few cases symptoms of severe general compression did appear, without there being present any very great effusion of blood inside the cranium; and in these the cause of the compression was evidently due to widespread reactionary swelling of the brain. Blood pressure would run up to 150 or 160, with pulse in the fifties, and the respiratory rhythm might show slight evidences of grouping, or even go on to the typical Cheyne-Stokes. At operation there would usually be found a fairly large hernia, and if the dural opening was slightly enlarged (a thing very rarely done), brain detritus would come pouring out, bringing with it occasionally pieces of in-driven bone, and even small shell fragments or a piece of cloth. The same might be observed on enlarging the wound of exit. The amount of destroyed brain tissue, which occasionally came out under pressure, was astonishingly large, and was a further indication, if any were needed, of the destructive effect of a high velocity bullet as the result of the radiation of force at right angles to its course. However, pressure was scarcely ever so great as to force out undamaged brain tissue through hernial openings, such as is sometimes seen after ill-directed decompression for cerebral tumors, or acute traumatic cerebral compression, in civil surgery. In other words, the amount of cerebral pressure was rarely, if ever, so great as to demand urgent relief by the removal of bone and a larger opening of the dura mater. Moderate degrees of compression could be relieved by lumbar puncture (provided it were carried out carefully), or by a contralateral decompression, though that was rarely necessary.

Symptoms of Local Injury, or Local Compression: It would be a work of supererogation in an article of this scope to recount in detail the symptoms referable to injury of well-known centers. Neurology is already the richer by a goodly store of knowledge in the domain of brain localization, as the result of the careful work of the English and French neurologists upon the injuries which the chance of projectile wounds has made wonderfully limited and precise. Attention should be called, however, to at least one new syndrome described by Col. Holmes and Col. Sargent[3] of the R. A. M. C. This has been called the longitudinal sinus syndrome, and is seen in tangential wounds of the vertex occluding that sinus. The cardinal symptom is a spastic paralysis in extension of both legs and sometimes in addition one, or even both arms, but not the face. In a typical case, the legs are stretched out rigidly, and rotated inwards, with feet crossed; the feet are extended almost in a straight line with the legs, and turned inwards; the arms are held tight to the body, elbows pressing on ribs, forearms flexed over the chest, hands clenched; fingers, wrists, elbows, and shoulders all rigid. The knee-jerks are much increased, and the extensor Babinski reflex is marked. The authors consider the condition to be due to thrombosis in the longitudinal sinus, or at least chiefly due to that. The prognosis under expectant treatment is quite good.

Lumbar Puncture.—As in the injuries of civil life, lumbar puncture was found to be of value in the diagnosis of subdural bleeding. In the case of small scalp wounds, when the question of penetration by a missile or of fracture of the inner table, without penetration, was in doubt, the finding of blood in the spinal fluid rendered this probable, though not quite certain. As a diagnostic measure, in suspected meningitis, its value was, of course, decisive, but undoubtedly the chief advantage of the procedure was therapeutic. For the last fifteen years certain surgeons of the French school have been advocating lumbar puncture, and the withdrawal of variable amounts of bloody fluid from the spinal canal, as a measure of decompression in cases of fracture of the skull in civil life. They have urged both the simplicity and the effectiveness of the procedure in reducing intracranial tension. While it is true that lumbar puncture will frequently relieve the effects of the lighter grades of intracranial tension, particularly headache, it has been felt by most of us that the measure was a dangerous one whenever the degree of cerebral compression was at all marked. The writer has seen in civil surgery two cases, and in war surgery one case, of sudden death with all the symptoms of bulbar paralysis following lumbar puncture. In one of these no more than 15 centimeters of moderately blood-tinged fluid was withdrawn and death ensued

within ten minutes. In the second case, occurring in the practice of another surgeon, the amount of fluid withdrawn was not measured accurately, but it was small. The third case, occurring in the writer's service during the war, was of such interest as to justify relating it in some detail.

The man was admitted to No. 1 Canadian Casualty Clearing Station at 11.15 A.M., April 1, 1916, with a wound in the right parietal region, above and behind the ear, and another wound, from which brain matter was escaping, over the vertex just to the right of the midline, and a third wound a little above the occipital protuberance. The two latter wounds represented the entrance and exit of a piece of shell casing striking tangentially. The patient was unconscious, all the deep reflexes were abolished, but the right abdominal reflexes were present. Respiration 18, and regular. Pulse 42. Blood pressure: systolic 138, diastolic 70. One hour after admission the writer did a lumbar puncture. The fluid was markedly bloody and under great pressure. As the fluid rose in the glass upright, fresh sections of tubing had to be added until finally a height of 1300 millimeters of water pressure was recorded; and this, too, after the loss of about a drachm of the fluid. This is the highest spinal pressure that the writer has ever observed or read of in the literature. The spinal fluid was gradually removed by small amounts at a time and under the control of measurements. Ultimately, during the course of nearly half an hour, a large test tube was filled, and the pressure was now reduced to 500. It was considered wise to stop at this point, so as to safeguard the brain from being pressed down into the foramen magnum. During the procedure the pulse kept between fifty and sixty, and at its close systolic blood pressure was 165. In spite of this precaution the patient began, within ten minutes to show signs of medullary paralysis, and died inside of half an hour, with falling blood pressure and rapid uncountable pulse. The brain was injected with formalin, through the carotids, two hours post-mortem, and autopsy showed a small amount of blood in the posterior fossa, the whole right cortex, except over the frontal lobe, covered from top to bottom by a flat clot in the meshes of the pia-arachnoid; the left side fairly free; no hemorrhage in the ventricles. A small furrow in the cerebellar lobes suggested pressure of the brain stem into the foramen magnum. The wound in the brain had been caused by a shell fragment of moderate size, which had entered just above the occiput on the right side, had traversed the right parietal lobe, and had gone out at about the region of the right arm area. A small piece broken off was lying in the cortex at this point.

While such cases as these warn us of the danger, in acute cases, of withdrawing more than a very few cubic centimeters of spinal fluid for the purpose of relieving a serious compression of the brain, it must be allowed that in the great majority of instances, and in the hands of careful surgeons, the withdrawal of a few cubic centemeters, under manometric control of the spinal pressure, has benefited the patient at least temporarily. In the author's experience a manometer pressure of between 200 and 400 millimeters was frequent in patients showing partial unconsciousness, moderate rise of blood pressure of 140 millimeters Hg. or below, and possibly slight slowing of the pulse. If such a spinal pressure were not reduced below 180 millimetêrs or better, 200, no ill effects ever followed; but as a matter of fact experience showed that such a relief of cerebral pressure only lasted a few hours, and was really not necessary. In the severer grades of cerebral compression threatening life (rare in any case), lumbar puncture was both insufficient and dangerous, and a classical subtemporal decompression was much to be preferred.

On the other hand the advantage of lumbar puncture was decidedly evident in the later stages, during early convalescene, particularly for the relief of the serious, even intractable, headaches from which the men suffered so much. The relief was often striking, but at first not lasting, and the puncture might have to be repeated several times.

In cases of meningitis, it was our custom to withdraw spinal fluid once or twice a day, both for the relief of headache and delirium, and as a sort of drainage of infective exudate. The procedure appears to have saved life in a few instances. It did so, seemingly, in one of the writer's cases; and it is certainly to be recommended.

Treatment.—(a) Scalp Wounds: Early in the war it was recognized that even minute scalp wounds, covered by a scab, not infrequently concealed a penetrating wound of the skull, from a small bit of shell fragment. Consequently it came to be the rule that all scalp wounds should be excised, and this the more as deep infection, under the aponeurosis, was common even with these tiny wounds. It was the particular credit of the Rouen group of hospitals, under Col. Gray, that they demonstrated the possibility, as well as the desirability, of excising and immediately closing practically all scalp wounds, save the very largest, using, if necessary, plastic methods. In a series of over 300 such cases, according to Col. Gray's statement to the writer, in 1916, primary union was obtained in all but about 3 per cent. The saving of time, expense, and service was enormous. The one important point in the operation is to make sure of cutting wide enough to be in healthy tissue, even at the expense of making extensive liberating incisions for closure.

(b) Cranial Wounds, without Penetration of the Dura: These were usually tangential wounds, cutting gutters in the scalp and bone, but they might be direct hits from spent missiles. In either case a small depressed fracture was common, with fragmentation of the bone into a mosaic. Discussion was rife as to whether or not, in the absence of symptoms of cerebral injury, it was advisable to trephine such cases and lift the depressed fragments, if the depression were slight, and if the *x*-ray did not demonstrate spicules of bone driven into the brain. Opinion, on the whole, was strongly in favor of trephining. After lifting the depression there would usually be found one of two things; either the dura looked quite healthy, or it was tense and the bluish look of subdural hemorrhage was visible through it. In the former case the operation should end with the replacement of the bone fragments (the wound having been thoroughly excised), and the closure of the scalp. In the latter case surgical opinion varied concerning the advisability of opening the dura. Sargent's opinion, with which the writer thoroughly agreed, was that it should not be opened. On the one hand the necessity of removing subdural clot, and possibly devitalized cortex, was not at all well established; while on the other hand there was always the possibility of introducing infection into the meninges from the dirty scalp wound. However, during the last two years of the war, when it had become customary to ex-

cise the edges of the scalp wound more carefully and more widely than was done at first, it was strongly advised by Willems, (4) Gross, (5) Harvey Cushing, (6) and others that the dura should be opened in such cases, and clot and contused brain removed, provided always the dura was immediately resutured. No harm ever followed this procedure in Cushing's hands, and it was his contention that convalescence, both as to relief of unconsciousness and early subsidence of paralyses, was very materially hastened thereby. In any case the dura should not be opened in these circumstances, save by the expert. As to the late developments of epilepsy, as the result of the non-removal of subdural clot and contused cortex, it is not yet proved that such an event is avoided by their removal. A cortical scar is inevitable in either case, as also meningeal adhesions at the point concerned; and these represent what are generally supposed to be the exciting cause of late epilepsy.

Penetrating and Perforating Wounds: Immediately the dura is penetrated, the outlook as to life becomes much worse, and treatment more difficult. The questions both of operative technique, and that of operative principles, have brought forth a great deal of discussion, and the methods of treatment have varied widely. First, as to the scalp incision. It was recognized from the first, and it still holds good, that the lacerated and dirty edges of the scalp wound must be excised in clean tissue. The knife is our best antiseptic. The next question is, naturally, shall one try to close the resulting defect in the scalp by primary suture? At first, on account of the general opinion that the septic track of the brain wound could not be efficiently sterilized, and that drainage of the brain was necessary, it was the practice to leave the wound open, except for a partial closure, and use it for the insertion of a drain. The drains themselves soon changed from the ordinary rubber tube, or cigarette wick, as used at first, to the perforated aluminium drain devised by Col. Sargent, which rendered excellent service. During 1915 efforts were begun, particularly by Col. Sargent, in the direction of primary closure of the wound in the bone and dura, through which a small cerebral hernia was very apt to present, largely in the idea of preventing further extrusion of brain. Sargent devised a small plastic operation on the aponeurosis, whereby he was able to cover the dural wound with flaps of the aponeurosis, at the same time instituting drainage to its neighborhood by one or two small rubber tubes inserted at the angle of the semicircular flap (which was the routine method of exposure during the first year or two). The principles laid down by Sargent in the first year of the war have been confirmed, save in a few points, by later experience. With the more frequent adoption of this procedure it became gradually evident that a very considerable number of the presumably infected wounds in the brain healed quite well without the development of an abscess, or encephalitis. Following this the remarkable results got by Carrel, Depage, and their followers, in securing primary healing, after early and thorough excision of wound tracks, led naturally to the attempt to secure similar results in brain wounds; and, whereas the principle of thorough excision of the scalp and the bony edges of the wound were already thoroughly accepted, it now became the object of endeavour on the part of a few surgeons to attempt a similar thorough removal of the disorganized brain, pieces of indriven bone, and foreign bodies, and then to do primary closure of the scalp. The practice gave such good results that it was largely adopted. During 1917 and 1918 the head operations that were done at Casualty Clearing Stations, that is, shortly after the infliction of the wound, were treated, as far as possible, with this object in view—thorough removal of the whole track of the wound with foreign bodies, the introduction of an antiseptic, and then immediate closure of the scalp, shutting off the interior of the brain from secondary infection, and trusting it to take care of itself.

A few words as to technique. This has been worked out chiefly by Sargent, by Gross, by Harvey Cushing, and also by Willems and Albert. Harvey Cushing's method is, briefly, as follows: in the scalp, after excision of the edges of the wound in healthy tissue, tripod incisions are made as a plastic method for later closure of the flaps by sliding. The area of bone injury in the case of depressed fractures is cut out *en bloc* by means of several burr openings around it, with the use of the Montenovesi forceps to cut the bridges. The dural opening is very rarely enlarged. The track of disorganized brain is now painstakingly removed by means of suction. A soft rubber catheter is carefully introduced along the track, and with a rubber bulb, attached to the end of the catheter, the disorganized brain mush is sucked into the eye of the catheter. The catheter is then withdrawn and the brain tissue pressed out. Sometimes small fragments of indriven bone are found to have been drawn in to the catheter with the brain tissue. The process is repeated until the operator considers that all disorganized brain tissue has been removed. Small fragments of bone are felt with the catheter, and these are removed with sinus forceps. Finally a small quantity of dichloramin-T is left in the cavity, and the flaps of scalp, sufficiently mobilized, are brought together, closing the wound entirely. A small cigarette drain is frequently inserted as far as the opening in the bone, but is removed after one or two days.

Willems summarizes his method as follows: In craniocerebral injuries with tearing of the dura and pulping of the brain, fragments are removed, foreign bodies extracted, the damaged area of the brain is cleaned out, and then the dura and the scalp are separately sutured without drainage. The open method is only resorted to when there is bleeding that can not be checked otherwise. He does not hesitate to enlarge the opening in the dura as much as is necessary for efficient opening. The most irregular rents in the dura can be accurately sutured by using a little patience. If it is impossible to close the structure entirely, the scalp is united directly over the gap left. If it is out of the question to remove a retained projectile, the dura and scalp are nevertheless united."

It is still not quite possible to form an accurate judgment as to the relative merit of the open and

the closed methods of treating these penetrating wounds of the brain. The degree of damage done, the locality where the wounds were inflicted (which has a bearing on the severity of the infection), the selection of cases for operation, the nature of the anaesthetic and the skill of its administration, the question of the steel helmet, the skill of the individual operator, and the conditions and quality of the aftercare, even the time and manner of transport, and finally the lapse of time from injury to operation, and whether operation was done at a Casualty Clearing Station within the first twelve hours, or at Base one to three days later—all these circumstances come in to cloud the issue and render judgment difficult. All that one can do at present is to submit a few figures and give expression to purely tentative conclusions. Willems' results in the case in which he carried out his complete primary closure were as follows: The number is small of those in which there was laceration of the dura and subjacent brain, thirteen only. However, all of these thirteen appear to have recovered. In eight both dura and scalp were sutured; in five the scalp alone; of the eight, seven recovered without any complication, while one had a small hernia, which developed at the end of a fortnight and disappeared after three lumbar punctures. Of the five there were three in which the projectile was left in situ, and these all healed. The two other cases had to be drained, but did well; one, after a superficial cerebral abscess had developed three times. He claims that it is easy to obtain primary disinfection of the brain by a careful removal of the pulped tissue with a curette, with which he says he is able to distinguish between sound and damaged cerebral matter. The writer's experience confirms this. The open method, with drainage, which was used by us, in the first two years of the war, was usually accompanied by a serious attempt to remove brain mush from the wound track, and the writer frequently used a blunt curette, with which it was quite possible to distinguish between sound and pulped tissue. Even a sinus forceps could be used without danger for the same reason, and with these instruments the most minute fragments of bone could be felt. Strong antiseptics were, however, not much used; but very good results were obtained, following Sargent's lead, with glycerine, which, through its hydroscopic properties, acted in much the same way as Wright's hypertonic salt solution.

Cushing's results were remarkable, particularly as showing the great improvement obtained with increase of experience, the development of better technique, and of good team work. His statistics include 250 cases treated at a Casualty Clearing Station between July 23 and Oct. 31, 1917, of which 219 were operated on; 20 were refused operation, as being hopeless; and 11 as not needing operation. Of the 219, 133 showed dural penetration. The mortality of the 133 cases was steadily lowered from 54.5 per cent. for the first 44, to 40.9 per cent. for the second 44, and to 28.8 per cent. for the third 45 cases. Cushing divides these 133 cases into six grades of severity. 1st, local depressed fractures of various types, with the dura punctured, 18 cases, 2 deaths (11.8 per cent.); 2nd, wounds usually of gutter type, with detached bone fragments driven into brain, 25 cases, 6 deaths (24 percent.); 3rd, wounds of penetrating type with lodgement both of projectile and bone fragments, 41 cases, 15 deaths (36.6 per cent.); 4th, wounds with ventricles penetrated or traversed, (*a*) by bone fragments, 14 cases, 6 deaths (42.8 per cent.); (*b*) by projectile, 16 cases, 16 deaths (100 per cent.); 5th, wounds of craniocerebral type, traversing the orbitalnasal or the auropetrosal region (meningitis common), 15 cases, 11 deaths (73.3 per cent.); 6th, through and through wounds, 5 cases, 4 deaths (80 per cent). The reader will notice from this excellent classification, the increasing danger of the operation with increasing severity of the wound. Where the ventricle is traversed by the missile, or where the missile passes through the brain from side to side, it is almost impossible to save life with any technique. On the one hand meningitis, proceeding from the ventricle, and on the other hand concussion effects, almost inevitably carry off the patient.

The writer is inclined to think that Cushing's block removal of the wound in the bone is unnecessary as a means of avoiding infection, and has the disadvantage of leaving an unduly large defect in the skull. The patient later is very apt to complain of the pulsating brain in this large defect, and to ascribe his headache and dizziness to the mere fact of the bone being lacking. Good results are obtained by rongeuring away the bone edges and leaving the defect as small as possible.

Cushing's figures apply to a Casualty Clearing Station. Operations conducted at the Base come under quite a different set of circumstances. The most complete figures that we have from the Base, in France, are given by Adie and Wagstaff, in the shape of a statistical report, published by the Medical Research Committee, in June, 1918, including 656 cases of head wounds. Those which involved penetration of the dura, not operated on before admission to the Base Hospital, numbered 236, and gave a general mortality of 49 per cent. Of the deaths, over three-quarters occurred within the first ten days after admission; and out of 81 cases so dying 54 showed no apparent septic changes at post-mortem; while, in the vast majority of cases dying after ten days, the cause of death was found to be some form of intracranial sepsis.

Late Results.—It has been the general idea that the late results of the penetrating head injuries, with regard to abscesses, paralyses, epilepsies, insanity, and various mental deficiencies, would very likely to be more or less bad. Such, however, has fortunately not been the fact. The first report of any large number of cases, examined late after the injury, came from Colonels Holmes and Sargent, whose article, published in September, 1916, is extremely interesting. They examined 1,239 cases of gunshot wounds of the head, admitted to eight London hospitals, and treated in France. Of these, 46, or 3.7 per cent., died, nearly all within three months of their arrival in England, and most within the first month. Post-mortems in twenty-two of these showed the cause of death to be in 10 meningitis; in 7 cerebral abscess; in one aneurysm;

in one secondary hemorrhage; in one late cerebellar hemorrhage, and in two pneumonia and haemothorax. They found that most of the paralyses, sensory and visual disturbances, etc., seen in the early stages, had been due not to local disturbances of the brain, but to concussion, edema, and vascular disturbances; and that consequently, in many of the cases many of the symptoms seen in France had disappeared. Even in the symptoms due to actual destruction of brain tissue, there had occurred, on the whole, a surprising amount of improvement. In the majority of cases the symptoms of mental deterioration, especially dullness, loss of memory, irritability, childishness, had disappeared. And on the other hand, actual insanity was surprisingly rare; in fact the number of cases they found was limited to two. Epilepsy likewise was rare. Fits occurred after evacuation to England in only 6 per cent. (37 cases) of 610 cases in which they had complete notes; and of these 37 the convulsions had been frequent in only 11. There was a large class of patients who continued to suffer from subjective symptoms, which could not be attributed to any local injury, the most common of which were headache, attacks of dizziness and nervous lack of control of emotions, temperamental changes, lack of concentration. These neurasthenic symptoms were quite independent of the site or severity of the original wound, and were recoverable. As to the healing of the wounds, here also the results were good. Where cerebral hernia had been present, which occurred, as a matter of fact, on an average of around 20 to 25 per cent. of penetrating or perforating wounds, there was a mortality of 24.16 per cent. in England, but in many the hernia had spontaneously receded and the wound had closed over. Of missiles retained in the brain at some depth, the total was 69 cases, of whom only four had died. In 76 per cent. of these the wounds were soundly healed and in 30 per cent. complete recovery had occurred without symptoms of cerebral lesions, while in 40 per cent. the neurological symptoms had improved to a remarkable extent; in 10 per cent. much disability still persisted.

Tuffier's figures confirm these observations. In 6,664 cases examined late, the results were as follows: epilepsy, local or generalized, 10.14 per cent.; late cerebral abscess, 1.41 per cent.; late meningitis, 0.48 per cent.; late cerebral hernia, 0.81 per cent.; deaths, 1.24 per cent. The reader may also consult Lapeyre (7) and Derache (8).

Medicolegal Notes.

Powers of Boards of Health.—The Michigan Supreme Court holds that the board of health of the city of Lansing, which has by charter all the powers and authority vested in health boards and health officers by the general laws of the state, did not have the power to locate a permanent pesthouse in a thickly settled residential district where, by reason of its location, it would be a nuisance.—Birchard v. Board of Health, Michigan Supreme Court, 169 N. W. 901.

Expert Testimony—Cause of Injury.—In an action on an accident policy physicians may testify that in their opinion a kink or loop in deceased's bowels resulted from external violence; but it would be improper for the experts to testify as to what actually did produce the kink; that was precisely what the jury were to determine, and was not the subject of expert evidence.—Budde v. National Travelers' Ben. Assn., Iowa Supreme Court, 169 N. W. 766.

Contract for Future Treatment—Patient's Inability to Receive Treatment.—A patient contracted with a physician for treatments at the physician's office, to continue for one month from a specified date, to be paid for in advance. He became too ill to attend the physician's office to receive the treatments. In an action for repayment of the money paid the New York Appellate Division holds that the physician, having incurred no expense in preparation for giving the treatments prior to the patient's disability, was required to return the money received. The court applied the rule stated in Fisher v. Monroe, 16 Daly, 461, 12 N. Y. Supp. 273, as follows: "The obligation of the party who is to receive the services to pay is conditional upon the obligation of the party who is to render the services to perform, and vice versa. If the contract of employment is to continue operative and binding, those interdependent obligations must continue to exist; and, if one party is excused from the performance of his obligations, the obligations of the other party must likewise come to an end." This rule, the court said, would seem to be equally applicable to both parties to a contract, where the services to be rendered and received were dependent upon the physical ability of the plaintiff to attend for treatment and of the defendant to give the treatment. In the event of illness of the defendant and his physical inability to perform, he would not have been liable for damages for breach of contract, but would have been obligated to return to the plaintiff the money paid in consideration of services subsequently to be rendered and not actually rendered. If, by reason of the defendant's inability to perform through no fault of his, the contract ceased to be binding upon the defendant, it became inoperative in like manner to the same extent in the event of similar disability on the part of the plaintiff. There was no evidence to support the contention that the money was paid as a retainer.—Bucklin v. Morton, 172 N. Y. Supp. 344.

MISSIONERS' ACCOUNTS OF EARLY AMERICAN EPIDEMICS.

THE medical profession has done little enough in the direction of enlightening the world as to the acute infectious diseases prevalent before and after the Spanish conquest of America and much interest attaches, therefore, to the researches of Efferts who has devoted much time to early ecclesiastical documents which should touch upon these subjects. An article telling of some of his recent researches appeared in *Janus* of January-February, 1919. The Portuguese who conquered in the Orient fell victims largely to the diseases of the conquered and subjugated races, while it is alleged that most of the Spanish conquistadores in America lived to an advanced age. But the natives after the conquest were visited by both variola and measles which they termed respectively great and small lepra. There was a third murderous epidemic which seemed never to attack the Spaniards and is not mentioned by name, which has greatly puzzled the antiquarians. The Mexicans regarded it as more severe than smallpox. The only affections one can think of in this connection are typhus and influenza, but this leaves much to be explained. Similar was the apparent immunity of the Spaniards in the first great outbreak of variola in 1520, although they knew nothing of inoculation or vaccination. Again the Spaniards escaped malaria, which prevailed extensively, although they had no quinine. Much seems to have been made by the missionaries over this alleged vulnerability of the native when compared with the immunity of the Spaniard, as showing that the Deity regarded with favor the Christian conquerors.

According to Sahagun, one of the Spanish chroniclers, the three great pestilential years were 1520 (smallpox); 1545 (the unknown plague which ravaged the whole of New Spain and killed most of those attacked); and 1576, in which another unknown plague made a still higher record, lasting but three months. While the author makes no such suggestion in his article, the speculator might do worse than identify the third pestilence with influenza, which only a short time afterward ravaged the entire Old World. It does not appear certain that the Spaniards were immune to this late epidemic. The strong no less than the weak suffered. According to Toribio the great measles year was 1531. Torquemada, in alluding to the great epidemics of 1545 and 1576, speaks of nosebleed as a prominent symptom. The word "tabardillo," as used by him, meant then only a burning fever, although now it indicates typhus. In 1688 another general pestilence is recorded while seven years later there was a recrudescence of measles, "tabardillo," and "paperas" (literally goiter). Cavo, a Jesuit, writing of the plague of 1576, states that it was not imported. According to him the Spaniards and their children were immune. The infection traveled from Yucatan to North Mexico. The natives were seized with severe headache and fever followed by states of fear and nosebleed. Death occurred on the seventh to the ninth day. The few who recovered were left in such a state of debility that ultimate recuperation seemed impossible. Not a native house in Mexico escaped a visitation. Some died of fear without having been attacked. Contagion could be traced from man to man. The physicians made many autopsies but could find no lesions, nor did the disease respond to any kind of treatment. Apparently the monks worked heroically to secure Christian deaths and burials for the afflicted natives. Spanish women and girls nursed the latter without contracting the disease. Some of the monks died, but only from overwork. Elsewhere it is stated that 2,000,000 natives perished of this plague (the epidemic of 1545 had 800,000 victims). In epidemics of such severity many deaths were due to mere starvation because few were left to provide food. From other sources we learn that in the epidemic of 1545 no less than 80 Dominican monks died; also that the Spaniards had the disease but in very mild form. It is therefore almost certain that the immunity of the Spaniards, remarkable as it was, was only relative. There is but little to add to the above data save that bloody stools are mentioned once or twice as an additional symptom. The reader can choose between typhus and influenza as the mysterious epidemic, or is at liberty to make any other guess.

SCHOOL HYGIENE.

THE depletion of the adult population by war has opened the eyes of the discerning of the community, among whom the members of the medical profession may be reckoned, to the necessity for not only conserving life, but for conserving life in a high state of efficiency, both mental and physical. In Great Britain the need for raising a healthy population and maintaining it at a high standard is fully recognized, and every effort is being put forth to accomplish this object. It is realized that in order to bring this about the people must be housed and fed well. An immense scheme for housing is now under way in Great Britain.

The crux of the problem is, however, the bringing up in a healthy way of the rising generation. Children must not only be fed and housed properly, but

the hygiene of the schools they attend should be of the best. Now the medical examination for war purposes during the past few years has proved convincingly that in all countries there is a large proportion of the population who are physically or mentally defective in one way or another. It has been stated on several occasions that 40 per cent. or thereabouts of the drafted men of the country were found unavailable for war service because of disabilities. This being the case, it is obvious that the greatest care must be taken in the rearing of children and of children at school.

Dr. James A. Nydegger, surgeon U. S. Public Health Service, read a paper on school hygiene as a national problem before the American Public Health Association, at Chicago, which was published in the *American Journal of Public Health* for June, 1919. He pointed out that the close relation which the public schools bore to national health would be best realized when it was understood that according to the last census there were 10,529,871 pupils in attendance at rural and city schools. Another fact which is not generally realized is that from 65 to 70 per cent. of the present-day school population belongs to the rural schools. Therefore, it is evident that the sanitation and hygiene of the country school should be as carefully supervised as that of the city school, and especially that rural school hygiene should be kept up to the highest standard. Notwithstanding the reputed superior healthfulness of the country, the death rate of cities is falling more rapidly than that of the country.

The reason for this is not far to seek. It is because the urban sanitation and hygiene are better than rural. Children are most susceptible to unhygienic and unsanitary conditions, and consequently it is imperative for the future of the race and nation that the country schools should be sanitarily above suspicion. Unfortunately, in the vast majority of instances, country schools, from the hygienic point of view, do not compare favorably with city schools. As a matter of fact, as Nydegger shows, the rural school is generally unhygienic and unsanitary. The building itself is too frequently unclean, ill-ventilated, damp, and poorly lighted, with a doubtful water supply. Emphasis has been given to these statements by the recent medical examinations conducted by the Public Health Service and other agencies, of a large number of school children in many States. The results prove the contention that an amazing number of children in rural districts are defective and in need of medical attention, and they further show that the health of the country child is from 5 to 20 per cent. more defective than that of the city child.

Unicistic Views of Influenza in Brazil.

While admitting to the full the wide disparities between pandemic influenza and endemic grippe, Carlos Seidl and many of his Brazilian colleagues contend that the two affections are one and the same. Seidl drew up several conclusions for discussion before the Academy of Medicine of Rio de Janeiro last October (*Revista Medico-Cirurgica do Brazil*, November, 1918) some of which were as follows: "Spanish influenza is only simple influenza, otherwise grippe. The endemic form may suddenly become virulent and pandemic. It exploded thus in Dakar on the west coast of Africa on September 10 and was carried to Brazil by a boat from that port. Endemic grippe is merely less diffusible, less contagious, less deadly. Pandemic influenza cannot be averted by sanitary measures because of unknown factors—meteorological conditions—which are beyond control. In its endemic aspect grippe, or at least all of the conditions which make it possible, are ubiquitous, and this state of affairs is also beyond control." The early date of these conclusions may be responsible for their adoption, for at a later period it was shown conclusively that the sufferers from a petty epidemic of influenza nostras in a certain locality in Brazil were soon after smitten by the pandemic and apparently received from the first visitation no immunity whatever. This experience converted many to the dualistic theory.

Mental Retardation Among Children.

There is a difference between mental retardation in the young and feeble mindedness, a fact which does not appear to be thoroughly appreciated by many medical men. In *Public Halth Reports* for April 11, 1919, Passed Assistant Surgeon Walter L. Treadway, U. S. Public Health Service, considers this phase of the subject and among other things points out that while heredity plays some part in determining whether an individual is a victim of retarded development or feeble minded, hereditary influence must not be wholly relied upon to decide the question. However, it is a factor and the person with such heredity should be regarded as possessing the so-called "neuropathic taint." Those with neuropathic predisposition probably are borderland cases, although they are very frequently brilliant and in consequence of their original turn of mind have added greatly to the world's store of literature, music and art. Environment too may have a good deal to do with retarded mental dedevelopment, as also faulty education. Treadway thinks that before a mentally retarded individual is diagnosed as feeble minded, it is essential to study him carefully and learn something of his total mental make-up. The borderland cases are well worth strict scrutiny, for it is only in this way that it will be possible to traverse the psychopathic twilight zone and that mental hygiene will occupy a high position in preventive medicine.

The Antiquity of Rickets.

Rickets has been generally regarded as a disease of comparatively modern origin. Francis Glisson deemed the condition to be new at the time that he wrote his remarkably accurate account of rickets, in 1650. Barlow, on the other hand, is of the opinion that "rickets was probably coeval with civilization." Ruffer has stated on many occasions that rickets existed among the ancient Egyptians, but Eliot Smith, another famous Egyptologist, thinks that he is mistaken, and that his views are far-

fetched. Dr. Leonard Findlay, writing in the *Glasgow Medical Journal* of March, 1919, holds that much of the evidence brought forward to show that rickets was coeval with civilization must be rejected as founded upon an unsubstantial basis. Nevertheless, if ancient literature be perused, analyzed, and dissected, there will be discovered passages which undoubtedly point to the existence of rickets. Of all the old writers, Soranus Ephesius, who lived between 98 and 138 A. D., discourses most clearly concerning a condition in children which is most probably rickets. All the symptoms are described with meticulous accuracy in his work on diseases of women. The interest of the work of Ephesius is that it seems to prove that rickets is of remote origin, and not, as believed by Glisson and his contemporaries, and also by the majority of the writers of the present day, as of comparatively recent date. It goes without saying that the environment and bad social conditions under which young children lived in far-gone days, or at least as it is thought they lived, especially in the decadent days of Rome, Egypt, and Greece, would foster and engender such a disease as rickets, whatever its specific etiological factor may be. According to Findlay, reliable ancient literature bears out this supposition, and rickets has existed as long as civilization.

Zinc As a Normal Constituent of Animal Tissues.

Attempts have been made with more or less success to prove that arsenic, copper, and other elements not classed as tissue constituents are normally present in traces in the animal organisms. Much, doubtless, depends on the constitution of the soil, for if these foreign substances occur constantly in the soil and find their way into the drinking water they may be found in traces in the bodies of men and animals. Recently Delezenne (*Annales de l'Institut Pasteur*, February, 1919), claims to have found traces of zinc in all of the organs and tissues of men and all animals examined. It occurs primarily in the formed elements of the blood to the extent of 15 to 25 mg. per liter. In the nerve centers, thymus, and other organs its percentage is lower. It may be demonstrated in all of the secretions and in animal food products, such as eggs and milk. Its presence to the extent of five parts per 1000 in cobra venom, with direct ratio between content and virulence, seemingly cannot be accidental, and the author believes that zinc is a necessary constituent of the tissue cell. It no doubt exerts a catalytic action on the splitting of lecithins and nucleic acid. The technique of the discoverer is, of course, of a special rigor and minuteness, and the author's colleagues regard the discovery as a scientific *tour de force*.

News of the Week.

Infantry Casualties Higher than Those of Aviation.—A report from the War Department states that the casualties among the infantry forces were higher than among aviators. In the infantry 55 officers and 46 of every 1,000 enlisted men were returned as battle deaths, against 31 officers and one man for the air service. The tank corps ranked third, with 16 officers and seven men per 1,000.

Bolsheviki Attack Hospital Train.—A communication from Vladivostok to the Associated Press, under date of June 17, states that a band of seventy Bolsheviki attacked a train, including American hospital and mail cars, near Spassk, north of Vladisvostok. Shots were fired into all the cars. None of the Americans were injured.

Advocates Division of Tuberculosis in United States Public Health Service.—Dr. David R. Lyman, in his presidential address before the National Tuberculosis Association at its recent meeting in Atlantic City, predicted the immediate creation of a division of tuberculosis in the United States Public Health Service. He believes this will be followed by the establishment at Washington of a National Department of Health. Plans were formulated at this meeting for a whirlwind Red Cross Christmas seal sale for the purpose of raising $6,000,000 with which to carry on an intensive fight for the prevention and control of tuberculosis. The opportunity which this will offer for an educational campaign to arouse the people of America to a realization of the economic menace of tuberculosis will be taken advantage of.

Farm for Open Air Treatment of Wounded and Sick Soldiers.—A farm consisting of 560 acres in Dutchess County has been purchased at a cost of $35,000 by the Community Development Corporation of New York City and will be used as a place for the care of sick and wounded members of the Seventy-seventh or Metropolitan Division. The place will not be under the control of the Government in any way. The community will be known as Dover Farms.

New Buildings for Jamaica Hospital.—The campaign that has been carried on in the Borough of Queens, New York, to secure $500,000 for the erection of memorial wings to the Jamaica and St. Mary's Hospitals, in honor of the men from that locality who laid down thier lives in the war, has been so successful that it announces that a new hospital building will be erected. The site for this institution will be in the vicinity of Woodhaven, which will make the hospital facilities accessible to a larger number of the residents of Queens.

Debarkation Hospital Closes.—Grand Central Palace, known during the past year as Debarkation Hospital No. 5 is to be closed and will be returned to the owners in the near future. During its six months of service as a hospital, 18,902 wounded American soldiers were treated there. Officers who were connected with the hospital state that the death rate was less than one per cent. In addition to the wounded many cases of influenza, pneumonia, and other diseases were cared for in the hospital.

Sea Breeze Home Opened.—Sea Breeze Home at Coney Island conducted by the Association for Improving the Condition of the Poor has been opened for the season. The association reports that thousands of applicants for fresh air relief have been received and that 300 convalescents and children under school age came to the home on the day of the opening.

Medical Service in the DuPont Munition Plants.—Beginning with the summer of 1914, on the out-

break of the war in Europe, it became necessary to increase rapidly the number of factories operated by this country and to extend the older ones. At this time the number of employees increased to about 150,000 and, as many of them were construction laborers hastily concentrated in isolated places, the sanitary problem at once assumed large proportions. An efficient sanitary service was organized along modern lines, and this has shown itself so effective that not a single outbreak of contagious disease has occurred to interfere with the production of munitions, the influenza epidemic excepted. Even here the approach of the disease was foreseen, and organized preparations resulted in better medical service for handling it so that those who became afflicted received better care than the limited supply of physicians in surrounding communities would otherwise have permitted. The isolated location of many of the plants made necessary the development of medical and surgical service to care for employees. On November 11, 1918, there were about a dozen hospitals in operation, and a total personnel of physicians and surgeons of more than 130. On a peace basis less than ten per cent. of this number will be required. This experience furnishes an interesting illustration of the advantages of organized medical and surgical care for industrial workers. Dr. A. K. Smith has recently been appointed Medical Director of the DuPont plants with headquarters in Wilmington.

Medical Society of the District of Columbia to Build.—The Medical Society of the District of Columbia announces its intention of providing itself with a building of its own. This society is one of the oldest representative medical bodies in the United States, having been founded in 1817, but it has never possessed a building of its own. The cost of the lot and proposed building is estimated at $90,000 of which about $50,000 has been subscribed by the members. An appeal is now being made to public spirited citizens to contribute the remainder of the sum necessary to carry out the enterprise. Dr. William Gerry Morgan is president of the society.

Health Officers' Conference.—The Health Officers' Conference which convened in Saratoga, June 23 and 24, was one of the largest meetings of its kind ever held in New York State, more than 1,000 health officers and over 900 public health nurses and social workers having been represented. Dr. Montgomery E. Leary, presided.

Some of the Allied Nations Slighted.—The New York State Health Department recently received a birth certificate registering the arrival of "Victor Italo America Franco Angelo————————." It was perhaps an oversight that a few of the allies are missing.

Dr. Edward S. Godfrey, Epidemiologist of the New York State Health Department, has returned from France, where he has been connected with the Red Cross in the capacity of Chief of the Health Inspection Service.

Superintendents of Protestant Hospitals Meet.—The superintendents and financial agents of many Protestant Hospitals in the United States held a National Conference on July 1 and 2 in Columbus, Ohio, to organize an association aiming at cooperation and general welfare. Seventy-six denominations were represented.

County Medical Society will Support State Commission.—The New York County Medical Society held a special meeting for the discussion of the narcotic drug problem on the evening of June 23. Resolutions were adopted offering the cooperation of the society to the State Commissioner of Narcotic Drugs in every legitimate and and constructive effort to do away with the drug evil. A letter from Dr. Copeland was read denying that any rules would be enacted independently by the Health Department, and stating that the only new regulations would be those of the State Commission.

Mount Sinai Hospital Files Plans.—Plans have been filed with the Building Department for an eight story addition to the Mount Sinai Hospital. The estimated cost of the addition is $500,000.

Aerial Ambulance Planned for Army.—The medical department of the army is planning to put into operation an aerial ambulance with a capacity of from two to fifteen patients. Major S. M. Strong, post surgeon of Carlstrom and Door aviation fields, Florida, is working on the plans and hopes to have the machine in operation in the near future.

The Rockefeller Unit which has been cooperating with the Red Cross in antituberculosis work in France, believes that it has accomplished its purpose in coordinating the work of various agencies engaged in that work in France and will return to this country in the near future.

Society Elections.—THE AMERICAN PEDIATRIC SOCIETY, at its annual meeting, held in Atlantic City, June 16-18, 1919, elected the following officers for the ensuing year: *President*, Dr. Thomas S. Southworth, New York; *Vice-President*, Dr. Alfred Hand, Jr., Philadelphia; *Secretary*, Dr. Howard Childs Carpenter, Philadelphia; *Treasurer*, Dr. Charles Hunter Dunn, Boston; *Recorder and Editor*, Dr. Oscar M. Schloss, New York.

THE AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION, at its annual meeting, held in Atlantic City, June 14-18, 1919, elected the following officers for the ensuing year: *President*, Dr. Lawrason Brown, Saranac Lake, N. Y.; *First Vice-President*, Lt.-Col. Charles W. Richardson, Washington, D. C.; *Second Vice-President*, Dr. J. N. Hall, Denver; *Secretary*, Dr. Arthur K. Stone, Framingham Center, Mass.; *Member of the Council*, Dr. Guy Hinsdale, Hot Springs, Va.

AMERICAN SURGICAL ASSOCIATION.—At the annual meeting, held in Atlantic City, June 16-18, the following officers were elected: *President*, Dr. George E. Brown of New York; *Vice-Presidents*, Drs. J. F. Binnie of Kansas City and Alexis Carrel of New York; *Secretary*, Dr. John H. Gibbon of Philadelphia; *Treasurer*, Dr. Charles H. Park of New York; *Recorder*, Dr. John H. Jopson of Philadelphia; *Member of the Council*, Dr. L. S. Pilcher of Brooklyn, New York.

Charitable Bequests.—The will of Mrs. Harriet Kingsland of Monmouth, N. J., bequeaths the sum of $10,000 to the Loomis Sanatorium and $5,000 each to the Association for Improving the Condition of the Poor of New York City and the Monmouth Memorial Hospital, Monmouth, N. J.

Obituary Notes.—Dr. Richard Ewell Brown of New York City died on June 14, aged 49 years. He was a graduate of New York University Medical School in 1894, a member of the New York Academy of Medicine, and surgeon to the Manhattan Maternity Hospital.

Dr. Joseph M. Doyle, a graduate of New York University Medical College, in 1892, connected with the Queens County Department of Health, and formerly resident physician of the Kings County Inebriate Home, died at his home in Brooklyn on June 14, aged 55 years.

Dr. Arthur Brigham Norton of New York City died of cardiac complications, following pneumonia, on June 18, aged 63 years. He was a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1881, a Fellow of the American College of Surgeons, a member of the American Institute of Homeopathy, the American Ophthalmological, Otological and Laryngological Society, surgeon to the New York Ophthalmic Hospitals, and oculist to the Hahnemann and Laura Franklin Free Hospitals. He was formerly president of the New York County Homeopathic Medical Society, and was founder and for ten years editor of the Homeopathic Eye, Ear and Throat Journal.

Dr. Edward M. McCoy of Charlotteville, N. C., died suddenly of heart disease on June 4, aged 47 years. He was a graduate of the North Carolina Medical College in 1894, and formerly practiced his profession in Huntersville, N. C.

Dr. Rosevelle Gardner Philip, a graduate of the Women's Medical College of New York City, in 1875, died after a long illness at her home in Stamford, Conn., on June 11, aged 72 years.

Dr. William Clark Payne, a graduate of the Western Reserve University Medical Department, in 1853, died at the home of a relative in Bozeman, Mont., on June 5, aged 88 years. He formerly practiced medicine in Marshalltown, Iowa.

Dr. Charles Fremont Cowan, a practitioner of West Hampden, Me., for 37 years, died at his home in that city on May 17, aged 63 years.

Dr. Alexander J. Stewart died suddenly of pneumonia, at his home in Provo, Utah, on May 28. He was a graduate of Queens University Medical Faculty, Ontario, in 1869.

Dr. T. Henry Becker, Jr., a graduate of Jefferson Medical College in 1911, and president of the Bluefields Sanatarium at Bluefields, W. Va., died suddenly in Philadelphia, where he was attending the commencement exercises of Jefferson Medical College, on June 7, aged 34 years.

Dr. Herman Wilcondar Katz, formerly of Brooklyn, N. Y., a graduate of the Albany Medical College in 1897, died at his home in Elizabeth, N. J., on June 19, aged 48 years.

Dr. William H. Carroll, founder of the Passaic General Hospital and St. Mary's Hospital, a graduate of New York University Medical College in 1884, died in the General Hospital, Passaic, recently, at the age of 58 years.

Dr. Harry J. Haiselden of Chicago, a graduate of the University of Illinois College of Medicine, in 1893, died of cerebral hemorrhage in Cuba, where he had gone for his health, on June 18, aged 49 years.

Dr. Thomas H. Tomlinson, a graduate of the Medical Department of the University of Pennsylvania, in 1859, died of pneumonia, at his home in Plainfield, N. J., on June 23, aged 82 years. He was a practising physician for more than sixty years, and a member of the original staff of Muhlenberg Hospital.

Dr. William C. Woolsey, formerly of Brooklyn, who served during the war as major in the Medical Corps of the United States Army, and recently returned from France, died suddenly at the Hotel Mohawk, New York, on June 23, aged 44 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1898.

Dr. John Newton Murdock, a graduate of Jefferson Medical College, died at his home in Leicester, Mass., on June 13, aged 92 years. He had served as representative of his district in the Massachusetts Legislature.

Dr. Frederick A. Chandler, formerly of Addison, Me., died at his home in Mechanics Falls, Me., as the result of heart disease, on June 10. He was a graduate of Harvard Medical School in 1883.

Dr. Arthur Howard McCray, State bacteriologist of Montana, died of spotted fever, contracted while doing experimental work on the disease, in a hospital in Helena, on June 15, aged 38 years. He was a graduate of George Washington University, Washington, D. C., in 1915. He was a lieutenant in the United States Navy Reserve Force.

Correspondence.

FURTHER EVIDENCE IN SUPPORT OF THE CONCENTRATED METHOD OF ARSPHENAMINE ADMINISTRATION.

To the Editor of the Medical Record:

Sir:—Believing that the greatest amount of good is done by hearing both sides of any controversy, and questioning the justice of the statement that one should be held responsible who fails to follow the method of arsphenamine injection prescribed by the Public Health Service, I desire to relate my own experience with the so-called concentrated method of administration. This extends over a period of about four years; to be exact, since July, 1915. At that time I used the imported preparation, giving 0.4 gm. in 50 c.c. of sterile distilled water, by means of a Luer syringe. The case histories of that series of patients are not now available, and I am uncertain as to their exact number. However, the facts are clear in my memory that I had no cases of acute collapse, none of cyanosis or dyspnea, and, in fact, nothing indicative of an anaphylactic phenomenon.

Again in 1917, at which time I had under my care a number of cases of nervous syphilis (paresis and tabes), I prevailed upon the pathologist to adopt the concentrated method, because the gravity method had proved too tedious for this class of patients. At my suggestion he procured a Ballenger salvarsan syringe (to be described later), and was highly pleased with the ease of administration, reduction of time, and absence of any alarming symptoms. The preparation used during this period was one made in Canada and marketed

under the name, I believe, of diarsenol. The results obtained in a small series of cases were entirely satisfactory, the preparation being apparently no more toxic than the German product.

The present series of cases, while small compared to the number reported by Dr. Nelken, in every respect are confirmatory of his conclusions. During the past year, beginning in July, 1918, I have personally given thirty-six intravenous injections by the method to be described, and my colleague, Dr. A. T. Hawthorne, has given seven by the gravity method and twenty-eight by the concentrated method. In other words, sixty-four intravenous injections of arsphenamine have been given by us, using the so-called concentrated method, without any of the mishaps for which a physician should be held responsible in the event they had occurred.

The method used by us is briefly as follows: Arsphenamine from 0.4 to 0.6 gm. Dermatological Research Laboratory product, is dissolved in about 30 c.c. of very hot, freshly distilled water, and neutralized by the addition of freshly prepared 15 per cent sodium hydroxide solution. It is then filtered through sterile cotton directly into a Ballenger salvarsan syringe, and sterile, freshly distilled water added, to the capacity of the syringe, care being exercised to maintain the proper temperature, viz., 98° F. The syringe used is that suggested by Dr. Edgar G. Ballenger of Atlanta, an Alexander type, with metal plunger and bayoneted joints. These joints permit the removal of the distal or needle end, and the filtering of the solution directly into the syringe. The needle coupling is situated at the edge of the circular distal end, and not at the center, as we have been accustomed to see on all other types of syringes. The instrument is graduated to 75 c.c., but with complete withdrawal of piston holds 100 c.c. We have been accustomed to fill the syringe to capacity in every instance. The needle is introduced directly into the vein with syringe attached, occasionally with the piston not entirely withdrawn, in order that a small amount of blood may be withdrawn into the syringe. More often, however, no blood is withdrawn, as we find a degree of expertness soon developed by which one invariably makes a proper entry into the vein. This is particularly true in male subjects with well developed veins. Great care is exercised to eliminate all air, and the solution is, of necessity, introduced slowly because of the small caliber of the needle used, the time required for the introduction of the solution being, as a rule, from five to seven minutes.

This procedure has been carried out by us sixty-four times with most gratifying results to both the operators and the patients themselves. In this small series of cases the majority of patients have had no reaction at all, and the few who did suffered only from vomiting and diarrhea. We have had no late reactions at all. In no instance have we noted collapse, cyanosis, dyspnea, or any other alarming symptom. In one case of cerebrospinal lues I adopted a modified Sachs method, giving the drug every fourth day, with no reaction except a slight headache on one occasion.

From my observation of both methods during the past four years I believe the administration of arsphenamine, as described above, is without any more danger than when administered by the gravity method in 30 c.c. of water per tenth gram of the drug. I further believe that any patient physically fit to have the drug at all may be considered a suitable case for this method. The simplicity of administration, the saving of time, and the almost universal absence of any reaction, even nephritis, has given us a confidence in the method which impels me to come to its defense.

One patient to whom I gave the drug last week approached the table with fear and trembling. Some three years ago he had been given the drug by the gravity method, after his vein had been dissected out. At the conclusion by the syringe method he expressed his satisfaction by saying, "You certainly know how to give it here." This man had no reaction, although he states that the dose three years ago "nearly killed me." I would further state that it has been my practice to precede arsphenamine treatment by about two weeks' mercurial therapy. Since adopting this method we have given no neoarsphenamine at all. Arsphenamine from the H. A. Metz Laboratories has also been used with equally gratifying results.

In closing, may I not call attention to the statement on pages 38 and 39 of the civilian manual for treatment of venereal diseases? Page 38 states that all preparations of arsphenamine, except the Dermatological Research product, are soluble in water at room temperature, and page 39 states that because of oxidation, shaking should be avoided. My experience has been that it is very difficult to get the drug into action without shaking it.

ROY A. THORNLEY, M.D.

WASHINGTON, D. C.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, June 5.

The Risk of Plague in Great Britain.—From the earliest days of international trade the five nations or governments most concerned, namely England, Holland, Spain, the Venetian Republic and Portugal, recognized that, whether they were already the possessors of plague at home, from their Eastern trade they might at any moment receive it. Quarantine began to be instituted, and when those governments who brought the art of quarantine to a high level are praised for their consideration of the health of their people, the other side of the picture must be recalled. Strict quarantine meant, perhaps, the deliberate condemnation of a whole ship's passengers and crews to a horrible death. If a ship infected with plague arrived, it was simply told to sheer off until it was no longer infected, when either a port was made where infection could be avoided or the ship returned to the East, the inmates dying by the way. If the crews, passengers and goods were landed in Europe, unsuspected plague followed their arrival. Of course, this is now ancient history, and the ports of the civilized world have a proper and common proceeding for dealing with infected ships—inspection, segregation, disinfection, reception at proper resting stations, due following up to their destinations of all who are allowed to proceed, and warning to the sanitary authorities at those destinations. Infection is al-

ways arriving at the great ports of the world, but the danger to the home populations is thus kept at bay.

But as the mass of infection which arrives gets larger in bulk in proportion with the increase in trade intercommunications, it is impossible not to wonder whether the safeguards of the two nations most exposed to risk—this country and America—are absolutely certain, and, as far as England is concerned, the recrudescence of plague in America gives point to such foreboding. The year 1917-1918, we learn from the recently published Annual Report of the Sanitary Commissioner with the Government of India, witnessed a melancholy rise in plague mortality throughout India. In most of the nine administrations the plague mortality has increased, the one bright spot in the dismal figures being that the Punjab no longer heads the disastrous list. But even now it remains third, and, as there have been three million deaths from plague alone in the Punjab during the past 20 years, it is clear that there is no longer so much inviting material for the attacks.

Such circumstances inevitably lead us to look closely at our defenses, especially in the great ports of Liverpool and Glasgow, and, while acknowledging the splendid work done by the sanitary administrators, to wonder if it is humanly possible always to maintain so effective a cordon against Eastern disease.

Our huge international trade connections make the arrival of a case of bubonic plague no rare happening at the great ports, and occasional cases come to light in the smaller ones. Recently a native member of the crew of a vessel which left Bombay early in April was found on his arrival at Liverpool to be suffering from plague, which he had contracted on the voyage from a soldier who had died off Gibraltar. The usual and rigid precautions were taken, and quite successfully, for there was no spread of the disease, but the circumstances have rightly engaged public attention. Thousands of soldiers are and will be returning from the East, and man shortage in administration quarters may make it difficult for all the usual watch and guard to be kept.

It is therefore good hearing that Dr. Addison, the president of the Local Government Board, was able to announce that a joint body representing the various medical, sanitary, and official services concerned was keeping the larger aspects of plague infection in mind.

Compulsory Greek for Medical Students.—Not so very long ago all physicians of university standing in Great Britain had at some time or other learned a little Greek. A hundred years ago there were only seven universities in the three divisions of the United Kingdom, and at all the graduate in medicine graduated also in arts, and therefore attained to that proficiency in Greek which is indicated by having industriously read some Homer, some Thucydides, and three or four tragedies, the hardly earned acquirement being lost and lost entirely in most cases within a year of the scholar's graduation. That was not the education in the humanities which after the Renaissance was to have made the learned man and the man of wisdom the same thing—it was a mere pretence to scholarship, and it was not surprising that as the new universities arose in the Victorian era they one and all discarded the notion of making Greek compulsory in their curriculum. But Greek still bars the way of the intending doctor at the University of Oxford, while at Cambridge Greek has only ceased to be compulsory by a few months. It is impossible not to sympathize with those of the Oxford authorities who wish to maintain Greek as a compulsory subject.

It would be a regrettable thing for Oxford to lose intending medical students of an intellectual caliber, which promised highly, because they knew no Greek and did not intend to learn Greek; but there is also something to be said for the view that if a man doesn't want to learn Greek he need not go to Oxford. Probably compulsory Greek will in the near future be abolished at Oxford, but the scientific protagonists of this movement must not rest on their oars—having done away with Greek they must take care to institute preliminary tests of corresponding stringency.

The Rural Housing Question.—I have frequently made allusion to the fact that medical men and sanitary authorities are sure that in the abominable housing conditions of many rural localities lies the *causa causans* of much of our epidemic disease, and many of our transmissible plagues. The Government is hard at work choosing sites for the new industrial houses, but so far it is chiefly the urban needs that have been catered for. Of course, these are the most pressing because of the number of individuals involved and the magnitude of the interests concerned.

But it would surely be a mistake to overlook the defaults of purely rural housing, and a notable pamphlet by Doctor J. C. Thresh, medical officer of the County of Essex, has just made a timely appearance, dealing with the home of the agricultural laborer in a county which, except its London suburb, is a purely agricultural district. Dr. Thresh shows clearly that in rural Essex there are in many districts not enough decent houses to go round, and in one district he found that 14 per cent of the houses were unfit to live in and could never be made fit, while 17 per cent, though unfit, might be improved so as to become habitable. What a story, is this of conditions in England in the twentieth century, and in an agricultural country, which must depend for its output and share in the national wealth on the good health of the agricultural laborer.

The Life-work of Charlton Bastian.—A pious letter from his son, appearing in the columns of *The Lancet* recently, called attention to the neglect of the theories and their proofs, put forward by the late Professor Charlton Bastian upon the origin of life. Tyndale and Huxley roundly stated their belief that Bastian was in error, and the so-called principle of "spontaneous generation" is generally considered to have had no scientific foundation. Surgeon-Commander Bastian's plea that his father's work should not be considered *chose jugée* has received the powerful support of Sir Ronald Ross, but recent work done at the Biochemical Laboratory at Cambridge and the Rothamsted Institute of Plant Pathology certainly indicates that Professor Bastian's technique betrayed him.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, May 14, 1919.

The Red Cross Federation.—The committee of scientists assembled by the committee of Red Cross societies, after careful consideration, adopted a formal minute as follows:

We have carefully considered the general purpose of the committee of Red Cross societies, whereby it is proposed to utilize a central organization which shall stimulate and coordinate the voluntary efforts of the peoples of the world through their respective Red Cross societies which shall assist in promoting the development of sound measures for public health and sanitation, the welfare of children and mothers, the education and training of nurses, the control of tuberculosis, venereal diseases, malaria, and other infectious and preventable diseases, and which shall endeavor to spread the light of science and the warmth of human sympathy into every corner of the world, and shall invoke in behalf of the broadest humanity not alone the results of science but the daily efforts of men and women of every country, every religion, and every race.

We believe that the plans now being developed should at the earliest practicable moment be put into effect and placed at the disposal of the world. In no way can this be done so effectively as through the agency of the Red Cross, hitherto largely representing a movement for ameliorating the conditions of war, but now surrounded by a new sentiment and the wide support and confidence of the peoples of the world, equipping it to promote effective measures for human betterment under conditions of peace.

We are confident that this movement, assured as it is at the outset of the moral support of civilization, has in it great possibilities of adding immeasurably to the happiness and welfare of mankind.

In addition to adopting this minute, the members of the Conference attached their signatures individually to a longer statement embodying the foregoing conclusions. Fifty-five specialists joined in this memorandum.

Child Welfare.—The future of the human race as represented by its greatest asset, children, was the local subject of one meeting. It was announced that the fundamental concern of the Red Cross should be the welfare of children. All other programs now being considered, such as tuberculosis, malaria, and the cure of other diseases, are intimately connected with the welfare of the child. Professor Pinard, of Paris, spoke on the lessons of this war in the injurious effects on women working while pregnant. In his opinion the mother should be free from responsibility of heavy work during the entire period. It was evident from the discussion that work for the care of children will form a most important part of the activities to be stimulated by the newly-formed international league of Red Cross societies. Discussion of the system of visiting nurses brought forth some interesting experiences.

Reports of subcommittees were submitted on tuberculosis, malaria, and nursing. The object of all of them is to present to the people in a practical, simple manner the latest and most authoritative knowledge of scientists.

Antituberculosis Work.—The final report of the section on tuberculosis of the congress represents the unanimous conclusions of the specialists for the guidance of the world in regard to combating tuberculosis. It will be presented to the peoples of all countries through the National Red Cross societies. The report says that the following factors are fundamental: (1) Dispensaries on an adequate scale furnished with laboratories and with specially trained visiting nurses, who shall carry into the homes of the patients the necessary care, instructions, and advice. (2) Careful and regular inspection of school children. (3) Hospital treatment for advanced cases. (4) Sanatorium facilities. (5) Popular education regarding tuberculosis.

The report says: "Tuberculosis is inextricably associated with the general living and working conditions of the people. We recommend the encouragement of all legitimate efforts directed toward the improvement of these conditions. We regard as of particular importance in this connection the care of children, the problem of housing, nutrition, and alcoholism. We recommend the institution of appropriate measures to prevent the transmission of tuberculosis through infected milk. We approve the establishment of open-air schools for the accommodation of children and the extension of the open-air system to practically all places where people are segregated, such as barracks, asylums, and orphanages." The report warns the public in regard "to the grave risk to which tuberculous patients are exposed through the exploitation of alleged cures without scientific authority."

At the close of one of the conferences of the committee of Red Cross societies Sir Arthur Newsholme, the head of the delegation of the British Red Cross, was asked for an expression of his opinion concerning these meetings. He said:

This conference has been the starting point of a movement which undoubtedly will have great influence on the future of the world. I have attended every meeting of the conference, and my general impression at the close of it is one of the greatest confidence in the eventual success of this movement. The great conception behind the conference is this: that a powerful, far-reaching, and beneficent organization born of war but essentially pacific in its objects, should not be demobilized because hostilities have ceased, but should be continued and even extended in time of peace. The idea is that prevention is better than cure, and it is our intention that the organizations which have done so much to *cure* suffering during war, shall *prevent* suffering, or at least reduce it to a minimum, in time of peace. To accomplish this it is necessary that all nations should cooperate. Disease knows no frontiers. The Red Cross societies provide the machinery by means of which this international cooperation can be brought about with comparative ease and rapidity. It is not intended that the peace time Red Cross societies, either in their individual capacity or as incorporated in the proposed international bureau, shall interfere in the slightest degree with the free action of any existing voluntary societies in the different countries. For instance, in Great Britain there are, among others, the National Council for Combating Venereal Diseases and the National Association for the Prevention of Tuberculosis, both of which are doing very good work and peace time Red Cross organizations would naturally not interfere with that good work. The principle of a Central International Red Cross Bureau, designed to enable all the indvidual Red Cross societies to pull together and mutually help one another in time of peace, has been definitely accepted, and the broad lines on which it should work have been laid down. There remains now to build up the necessary organization in conformity with the requirements of our common ideal.

"Euthanasia."—The usual and inevitable pro-

tests have followed the statement by a member of the Chamber of Deputies that he had no doubt a time would come when painless anesthesia would be brought about for those suffering from incurable and agonizing diseases. It is a difficult question and involves a good deal more than appears at first sight.

4. The Diagnosis of Earache.—Hugh B. Blackwell divides cases of earache into the following four groups, basing his classification on anatomical, etiological, and therapeutic grounds. (1) Those produced by an inflammation behind the tympanic membrane, the infection originating in the nose and throat and being introduced in the middle ear by way of the Eustachian tube. The attack is usually preceded by inflammation of the upper air passages and an aural examination reveals a more or less inflamed or bulging drum head. This may be covered with a white necrotic epithelium, which on being removed reveals an underlying deeply injected membrana tympani, very sensitive to the touch of a cotton wound applicator. The pain of a middle ear abscess is steady and boring in character, more or less continuous, and is located directly in the ear. As a rule, it is relieved only by incision or spontaneous rupture of the drum. (2) Those produced by inflammation of the soft parts of the external auditory canal, commonly known as external otitis or furunculosis. This condition may develop as a result of scratching, from faulty attempts to remove wax, or frequent submersions in salt water causing excessive dryness of the auditory canal epithelium. Aural examination reveals a swollen and sensitive external auditory canal. The drum head may be observed by careful use of a small speculum and frequently shows some sympathetic congestion but is otherwise normal. The tragus or auricle is very sensitive and the pain is usually increased by mastication, which is a valuable differential point. There is often slight painful enlargement of lymphatic glands situated about the auricles, and the pain is more throbbing in character than in cases in the first group, and is usually increased by lying down or leaning forward. (3) Cases of otalgia, in which there is no inflammation, the pain being neuralgic and reflex, referred from the teeth, nose, or throat. Patients are often neurasthenic. As a rule, the pain is not located directly in the ear and is less intense than in the other groups of cases. (4) Those cases in which the earache is largely mechanical and which occurs principally in children and infants with enlarged tonsils and adenoids. The pain is nearly always nocturnal, recurring several nights in succession. The etiology is as follows: the prone position of the sleeping patient increases the congestion in the nasal pharynx, resulting in temporary closure of the Eustachian tube, thereby converting the middle ear into a closed cavity; the blood circulating in this cavity absorbs its contained oxygen and induces negative pressure. The eardrum retracts sharply and the child awakens suddenly with an earache and begins to cry. The act of crying forces open the Eustachian tube and relieves the pressure and the pain soon ceases. Aural examination shows the membrana tympani to be normal, save for retraction and possibly some congestion during the attack. Of course earache may be produced by a combination of these factors, *e. g.* furunculosis of the canal associated with an acute or chronic middle ear abscess. In such cases the clinical evidence is of great value. The author emphasizes the importance of early diagnosis so that proper measures may be instituted and, if possible, the subsequent development of such a severe complication as mastoiditis prevented.

6. Intravenous Injections of Foreign Protein in Influenzal Pneumonia.—Clifford W. Wells reports the results obtained from the intravenous injection of a foreign protein in eleven cases of influenzal pneumonia. With two exceptions, the cases selected for treatment were critical, leucocyte counts being definitely of the leucopenic type, the aim being to provoke a leucocytosis. The protein used consisted of typhoid bacilli, macerated and exposed to the soluble action of alcohol for twelve hours, washed free of alcohol and suspended in physiologic sodium chlorid solution, the concentration being the equivalent of approximately three million bacilli per cubic centimeter. The dose employed was sufficient to produce a definite, so-called protein reaction, as a rule 1 c.c. Leucocyte counts were made previous to the injections, and from four to twelve hours following the reaction. In several cases blood chemistry determinations were made before and after the injections. From thirty to forty-five minutes after the injections the patients experienced a typical protein reaction, characterized by a severe chill and moderate cyanosis, lasting from fifteen to twenty minutes and followed by a period of profuse sweating and marked elevation of temperature. Shortly after the period of sweating, patients invariably felt and appeared much better. Of the eleven cases, eight showed an increase in the number of leucocytes, but in only five was this worth noting. In the latter cases there was an increase in the proportion of polymorphonuclear leucocytes. The three cases with slight increase in the number of leucocytes recovered, as did the two mild cases included in the series. Of the remaining nine cases, four died, two however from empyema. No deleterious effects could be determined from these injections as regards increased retention of products of katabolism, which is in accord with the findings of McQuarrie and Whipple. There was increase of blood pressure in two cases. The author refers to the importance of polymorphonuclear leucocytes in immunity against bacterial infections, as emphasized by Metchnikoff and his school. In view of the low leucocyte count in most cases of influenzal pneumonia, it seemed logical therefore to attempt to stimulate an increase of these cells. Although the number of cases treated was small, the author believes that the intravenous injection of foreign protein is efficacious in selected cases when made by one thoroughly conversant with all the possibilities of the therapy. He states, however, that such injections should not be employed as a routine by the general practitioner.

1. The Croonian Lectures on the Rôle of the Sympathetic Nervous System in Disease. Lecture III.—W. Langdon Brown discusses the question of the relationship of the blood sugar to glycosuria and the influence of the sympathetic and endocrine glands upon them. He points out that diabetes should be considered a disease of metabolism as a whole, although the carbohydrate disturbance probably precedes the others. He takes Allen's slight modification of Pollak's classification of glycosurias as a basis for discussion, namely: A. Glycosuria resulting from renal action: (a) without hyperglycemia, e. g. phloridzin poisoning; (b) with hyperglycemia, renal poisons, e. g. uranium. B. Glycosuria resulting from hyperglycemia: (a) independent of glycogen content of the organs—diabetes; (b) dependent on glycogen content of the organ and caused by sympathetic stimulation—(1) central (analogous to puncture of the fourth ventricle), caffeine, strychnine, asphyxia, and stimulation of sensory nerves; (2) peripheral, adrenalin. As suggested in this classification, renal lesions may lead to either increased or decreased permeability of the kidney to sugar and it is probable that remedies such as uranium, employed to diminish glycosuria, really do so by damaging the kidney. There is also a condition of hypoglycemia with glycosuria, to which Salamon gave the name "diabetes innocens." Such cases, however, must not be looked upon as necessarily non-progressive, as some undoubtedly do pass into typical diabetes. Allen considers diabetes as a definite entity sharply contrasted with all other forms of glycosuria, and defines diabetes mellitus as the condition resulting from the reduction of the pancreatic amboceptor below the requirements of normal metabolism, basing this mainly on the anti-diuretic effect of parenterally administered dextrose and its paradoxical law of its assimilation in the non-diabetic, even though glycosuric, organism as opposed to the diabetic. After discussing in some detail the rôle of the pancreas in the production of diabetes, the author points out that oversecretion of the pituitary gland always lowers the tolerance for sugar and may excite a frank glycosuria, or the sympathtic nervous system may produce glycosuria through stimulation of the pituitary, as was shown by Weed, Cushing, and Jacobsen. Thyroid extract is also known to excite glycosuria, and this condition in pregnancy is probably due to the stimulating effect of pregnancy of the thyroid and the pituitary. There is also experimental evidence that glycosuria can be excited by excess of adrenalin, although there is very little clinical evidence of a definite adrenal diabetes. It may be concluded that underaction of the pancreas or overaction of the adrenal, thyroid, or pituitary can all lead to glycosuria. But if there is no disease in any one gland the question arises as to how the loss of balance is brought about. The author calls attention to the way in which this could take place through the sympathetic, stimulation of which increases blood sugar as a defensive measure, causes increased secretion of adrenals, thyroid, and pituitary and in its general effect is katabolic. By increasing the secretion of glands which diminish carbohydrate tolerance and inhibiting the gland which increases this tolerance, the sympathetic raises the blood sugar above the leak point and this results in glycosuria. Brown suggests that the failure of the carbohydrate of the food to be assimilated owing to defective action of the internal pancreatic secretion would produce far more profound disturbance of metabolism than the increased action of glands which simply increase the sugar mobilization, because the action of the latter would be limited to that on the stored carbohydrate in the body, which does not reach a large amount. This accords with the fact that pituitary and thyroid glycosuria are more amenable than the glycosuria dependent upon frank pancreatic disease, and explains why spontaneous diabetes resembles pancreatic diabetes more closely than the glycosuria arising from any other endocrine gland. Yet Allen says the diabetic may have as good a pancreas as any one else. Allen suggests the following as the most reasonable classification of persistent glycosuria: (1) *Organic origin*, with structural changes in the endocrine glands leading to (a) overaction of adrenal, thyroid, pituitary, or (b) underaction of pancreas. (2) *Sympathetic origin*, with no evidence of structural changes in any endocrine gland, but producing a functional (a) overaction of adrenal, thyroid, pituitary; and (b) underaction of pancreas. This really makes spontaneous diabetes a disease of the nervous system, which the author points out is not a new idea. The author's final conclusion is that diabetes is due to deficiency of the pancreatic amboceptor, which deficiency may be due to structural changes in the pancreas, or to inhibitory action of the sympathetic on its internal secretion, an effect which may be aggravated by sympathetic stimulation of other endocrine glands, thus further diminishing the power of carbohydrate assimilation.

7. Abstract of the Harveian Lecture on Nerves in Amputation Stumps.—Edred M. Corner draws attention to the fact that nerves, as contrasted with other structures, have the peculiar power of regenerating. They grow again so as to re-innervate, or neurotize, a part that has been de-innervated. In the case of amputations, the de-innervated portion has been removed, robbing the regeneration of its object. The result is that the growth is wild, and it invades every contiguous structure, such as bones, vessels, muscles, etc., exhibiting a pseudo-malignancy, and by growing between the cells defeats all methods devised to arrest the progress of regeneration. This fact, if borne in mind, may stop much waste of surgical energy and time. The immediate pain consequent on an amputation is due to the injuries inflicted on the nerves at that operation and passes away in a few days. Early pain after an amputation is due to the ends of the nerves, if not cut short, taking part in the general repair of the wound. If the repair is infective, there is infective neuritis. If precautions are taken to cut the nerves short and close their open mouths in a simple way, as by the swing-door method, the interior of the nerves is not infected from the wounds. From this the following practical points arise: (1) Cut short the divided nerves. (2) Close the mouths of divided nerves. (3) Avoid all wound infection by avoiding handling and manipulation, which are the great causes of low-grade infections such as are not necessarily suppurative. The healing of a wound by first intention in clinical work does not preclude the presence within it of low-grade infection. Nerve anastomoses mean much manipulation and are therefore banned. The following factors are now known to be concerned in the causation of remote pain: (1) Infective inflammation and its results, islands of fibrous tissue, within the nerve. Cultures have been obtained from nerve endings three years after complete healing of the wound, and the organisms were shown by Professor Marinesco at the meeting of the Royal Society of Medicine in April, 1918. (2) The presence of foreign bodies, including metal, silk, and all material such as fibrous tissue in the interior of a nerve ending. (3) The mental factor, due largely to illness, prolonged hospital stay, lost jobs, inability to take up new ways and interests, etc.; this is a very large factor and is probably larger in people who have lost limbs than in others. There may be

other factors, such as that due to vessels trying to expand or contract in tissues permeated by fibrous tissue, but at present their clinical importance is unknown. Therefore: (1) Do not use silk in infective wounds. (2) Do not keep men herded together in homes and hospitals longer than necessary. (3) Get them back to some kind of work, which will absorb their attention and take it off their condition, as soon as possible. Corner furthermore points out that if a wound heals quickly and well, there are very few organisms in the scar tissue which forms in the "dead space" under the saw divided end of the bone. If, however, this space is filled with irritant infective scar tissue and there is deep suppuration, the bone is irritated and new bone formation takes place, the muscles are irritated and become reattached, resulting in pains in the stump which cannot bear pressure, slowness in healing with local edema and inability to encapsulate foreign material, such as silk or iron. This infective scar tissue is slowly sterilized by the body fluids, but if it remains irritant the new nerves formed by regeneration grow into it and the equation of nerve plus inflammatory focus equals pain becomes satisfied. Sensations, falling short of pain, but responsible for phantom limbs, may result if a new ill-protected nerve fiber comes in contact with a focus of repair. The clinical fact that operation fails to remove such pains at once is easily understood when it is remembered that the operation itself leads to repairs in nerves among other structures and that the patient has stored up memories of past operations, pains, and phantoms. Operation, however, often brings about some alteration, as in the phantom which has become immovable, and then there is hope. The branching and anastomoses of the new nerves must lead to many complicated brain stimuli and this must lead to frequent variations in the quality and quantity of the sensations and symptoms so produced. The difficulty encountered by the nerve in progressing through actively proliferating scar tissue is shown by the nerve spirals and button-shaped nerve ends. In suturing nerves, therefore, the ends should be so approximated that little scar tissue can be formed for the nerves to grow through. Apparently they grow through muscle more easily, but make little headway through connective tissue. Finally, the great cause of pain is inflammation, and the causation of phantoms lies in the mind, possibly in the association of foci of repair with nerves.

1. Acute Encephalo-myelitis. A Clinical and Experimental Investigation of an Australian Outbreak.—J. B. Cleland and Alfred W. Campbell have examined clinically 134 cases of "the mysterious disease," as this epidemic was first named by the newspapermen, and the tissues from sixteen fatal cases; they have also made a long series of animal experiments, coupled with exhaustive histological examination of the tissues. The present paper contains the salient findings of these observers together with their thesis for judgment. They summarize their report as follows: 1. *Clinically.*—An account of a form of encephalomyelitis, occurring as an epidemic in the late summer of 1917 and 1918, confined almost entirely to certain dry inland parts of New South Wales; appearing as an acute and severe illness, often abrupt in onset, and fatal in 70 per cent. of cases; affecting children mainly but not sparing adults; characterized by general signs of cerebro-spinal irritation—namely, convulsions, rigidity, heightened reflex excitability, mental obfuscation, and loss of consciousness; accompanied by fever and gastric and other disturbances; terminating in exhaustion, coma, and death in a few days, or in rapid recovery, usually complete, but in a few instances attended by flaccid paralysis or mental disorder. 2. *Histologically.*—Exhaustive microscopic examination of the nervous system in 16 cases showed acute encephalomyelitis, universally distributed; characterized by vascular engorgement, "sleeving" of veins with lymphocyte-like cells, isolated "colonies" in and infiltration of the tissues with similar cells, and a tendency to capillary hemorrhage; affecting grey substance more than white on account of the difference in vascular supply; and seldom grossly destructive as in "acute poliomyelitis." 3. *Experimentally.*—By intracerebral inoculation of an emulsion of portions of the parent nervous system the disease has been conveyed from human subject to monkey (*Macacus rhesus*); from monkey to monkey, in series; from monkey to sheep; from sheep to sheep; back from sheep to monkey; and on again through monkeys; and lastly, from monkey to one horse and one calf—all of which results were confirmed by histological examination, showing changes unequivocally corresponding with those found in *homo*. 4. The disease in monkeys was eminently fatal, and was mainly characterized by weakness, drowsiness, and intense incoordination of movement. Flaccid paralysis was not a dominant feature. Some sheep gave no response to inoculation, others showed slight or no signs of disease, proving a certain degree of immunity. In the "positive" sheep convulsions commonly caused death. The inoculated horse and calf also died from convulsions. Cleland and Campbell conclude therefore that the disease, from the anatomical standpoint may be called "acute encephalomyelitis." They point out that it resembles "acute poliomyelitis" and "encephalitis lethargica" inasmuch as the responsible, undiscovered virus has an evident affinity for the central nervous system; probably requires incubation therein, under favorable conditions, to perfect its nocive power, and produces histological changes which follow the blood vessels, hence suggesting that all three diseases may be due to mutants of the one virus. On the contrary, however, the individuality of this epidemic; the preponderance of signs of cerebrospinal irritation; the high rate of mortality; the common affection of adults; the infrequency of paralysis of cranial or peripheral nerves; the widespread changes in the nervous system without gross focal lesions; the susceptibility of the sheep, horse, and calf, as well as the monkey; and the reproduction of preponderating signs of cerebral irritation and of the human histological changes in all these animals, favor the conclusion that the disease is a distinct entity.

3. Congenital Edema.—David M. Greig describes a case of congenital edema in a child six weeks of age as follows: The edema which was noticed at birth was strikingly symmetrical. It formed on the dorsum of each foot a very prominent swelling, more exaggerated and obvious to the lateral than to the mesial aspect of the foot, and more pronounced toward the toes than toward the ankle. The prominent mass appeared to overhang the fifth metatarsal and to bulge forward over the toes. The toes themselves were involved in the edema, giving them the appearance of being fat and "podgy," while the transverse grooves marking the metatarsophalangeal and the interphalangeal joints were deeper than usual. On the plantar aspect each foot was full and slightly convex from side to side, and the transverse lines were absent or less marked than normally. The skin over the areas involved was smooth and had a distended appearance. At its maximum the swelling on the dorsum would be fully an inch in depth. The edema did not pit easily on pressure, and was peculiarly firm and resistant. It was not noticed that the

feet were less warm than natural, and there was no discoloration nor dilatation of vessels. No enlarged lymphatic glands were anywhere observable. Congenital edema undoubtedly of rare occurrence. There is not a large number of cases on record. All the more need, then, to view this condition in its true perspective. Whether it was first recognized in France or America is of little moment, but there can be no doubt that to Milroy is due the credit of first bringing the existence of hereditary edema clearly before the profession. Milroy puts the characteristics of the disorder succinctly thus: 1. Congenital origin with a steady growth corresponding to the normal growth of the body until adult size is attained. 2. Limitation of the edema to one or both lower extremities, the areas involved varying. 3. Permanence of the edema. 4. Entire absence of constitutional symptoms. Milroy records the condition as one of angioneurotic edema. There is a difficulty in accepting this suggestion. Greig does not think that congenital edema fulfills the conditions generally accepted as characteristic of ang.oneurotic edema. Angioneurotic edema is an affection probably due to nerve influence on blood vessels. Hence its name. It is a more or less transient temporary affection, though one can conceive how many attacks may result in persistence of some of the swelling and its accompanying inconveniences. It indeed shows at times a tendency to be hereditary, and that it may originate in the absorption of intestinal toxins is probable in those cases in which gastrointestinal disturbance is pronounced. It appears to be an entirely different condition from either congenital or hereditary trophedema. Isolated cases of congenital edema may even form a third condition, or it may be the first instance of what is to become later an hereditary defect. Its character and its progress suggest some local symmetrical congenital defect in the lymphatics rather than a vascular affection whether neurotic or otherwise in origin. The condition is distinct from that inequality of limbs not unfrequently found in new-born infants in which one limb or part of it appears unduly fat and the grooves at the joints are deeper than usual, for in this condition there is no edema and the parts are normal to touch and not firm. The condition is distinct from unilateral hypertrophy, in which the determining factor of the overgrowth is very probably a central nervous affection secondarily involving alterations of blood vessels in fetal tissue. Finally, the condition is also distinct from progressive subcutaneous edema, in which there is probably an ascending lymphangitis and perilymphangitis, bringing about lymphatic obstruction, and characterized by its late onset and its steady progression. Not enough cases have yet been gathered and investigated to place congenital trophedema on a proper basis, and until a sufficient number have been placed on record the pathology of the condition is bound to remain obscure.

6. The Treatment of Sinuses Persisting After War.—Arthur J. Turner states that the majority of sinuses persisting for any length of time lead to the surface from bones which have been damaged by one or other kind of missile. Sometimes they do not, and then it is usually a metal fragment or a piece of cloth or some other foreign body remaining in the tissues which is responsible for non-healing. In cases where bone is involved, it may be a small splinter of bone from the external surface, or soft necrosing or necrosed bone tissue of greater or less depth into the structure of the bone, or a sequestrum lying within the bone which keeps the sinus open by a constant discharge of pus. In dealing, therefore, with the problem of such sinuses, with the object of bringing to a speedy termination this discharge of pus and the prolonged series of frequent dressings usually employed in these cases, it is of first importance, as in fresh wounds, to remove as completely as possible any foreign body, diseased or dead tissue as may be concerned in producing and perpetuating the sinus. Turner has up to date dealt with 110 cases. For the very successful postoperative treatment of these he is deeply indebted to the illuminating article of his former teacher, Professor Morison, on "The Treatment of Infected, Especially War, Wounds," in the *British Medical Journal*, October 20, 1917. The paste used by Turner differs from that described by Morison as "Bipp" in more than one detail, but that is partly due to his dealing with operated wounds where circumstances made it impossible to draw the tissues together with sutures, and where, moreover, he was anxious to obtain granulation from the bony surface outward to avoid leaving a cavity within, which one could not feel certain was being filled up. With this object, therefore, he added to his paste a small amount of scarlet red powder, the property of which in stimulating growth of granulation tissue is familiar to most surgeons. Turner, however, has adopted Morison's technique of drying out the wound with gauze, applying to every cavity and crevice methylated spirit, and then gently rubbing in the paste very thoroughly over the whole surface of the wound; finally applying a dressing of gauze, either dry or moist with spirit, after having painted the surrounding skin with tincture of iodine made with 70 per cent. alcohol. In addition to the remarkably good results obtained, Turner thinks that sufficient emphasis perhaps has not been laid on the desirability of Morison's method of treatment from the point of view of economy. At a time when surgeons, nurses, and orderlies were greatly overworked, and when the demand for all kinds of dressings was so extensive and so imperative, it was of the utmost importance that greater use should be made of a method by means of which Turner has no hesitation in saying the time given to dressing wounds and the expense of the dressings themselves might be reduced to a fraction of what is employed in the old way. He found that there was by the introduction of the paste method a saving in his hospital of over 44 per cent. of gauze, 18 per cent. of boric lint, 41 per cent. of plain lint, and 31 per cent. of cotton wool. There was also a saving of 49 per cent. of bandages, but this was partly due to the sterilization and repeated use of all bandages, however soiled; so that none was wasted except those that out-patients failed to bring back. It should be borne in mind that the wounded patient suffers from the effects of pain upon his nervous system, and of suppuration sapping his strength by the drain of leucocytes from his tissues and the absorption of toxins into his blood stream. A method, therefore, which does away with painful daily dressings and reduces the flow of pus to a minimum serves the important purpose of promoting a speedier restoration to health, and in fact a quite noticeable improvement takes place soon after the operation stage is over.

Circumscribed Osteocartilaginous Lesions of the Knee Joint.—G. Axhausen studies the state of chronic irritation following certain injuries of the knee and which manifests itself by weakness of the joint and a tendency to recurring fluid collections. Usually the process is a lesion of the cartilage followed by mortification and then the formation of a free body in the joint. In other cases a simple osteo-cartilaginous detachment takes place under the lining membrane of the joint. The usual points to look for these lesions are the posterior surface of the patella and the convex aspect of the femoral condyles. Cinetic anatomy shows in fact that any form of shock directed from in front backwards acting on a flexed knee produces a brutal contact of these two articular points. The state of chronic irritation results in a chronic congestion of the zone of junction between the bone and cartilage, from which arises pain and attacks of exsudative arthritis. Operation, which is the only means of rapid cure, should do away with the free bodies in the joint when they exist, shave off the irregularities on the articular surfaces, or even completely remove a detached and mortified cartilage plaque. It must not be forgotten that in some ways this process is similar to circumscribed arthritis deformans and that it may have the same serious prognosis as the latter lesion.

"Nil Nocere," a Contribution to the Treatment of Influenza.—Zadek perceives a danger in the polypharmacy resorted to in the present epidemic. Modern chemotherapy and serotherapy have resulted in the oblivion of precepts of general treatment which are certainly important. Abstention from drugs, which the writer advises, should be particularly severe in the case of opium derivatives which calm the cough,

but favor the extension of pulmonary infections. Rest in bed is particularly bad. The sitting position is the best preventative for bronchopulmonary lesions. The writer also advises cutaneous revulsion, sudation, etc. From what is said in this paper one may conclude that elementary medications seem to have fallen into oblivion in the land of chemotherapy *par excellence*.

Münchener medizinische Wochenschrift.

March 21, 1919.

Changes in the Cerebellum in Typhoid Fever.—W. Spielmeyer describes small rosette-shaped foci or gliomatous arborizations seated in the superficial stratum of the brain and cerebellum in cases of typhoid. The cerebellar changes, which are more particularly the object of the paper, were found in five cases of typhoid which came to autopsy. A comparative study of other infectious diseases, such as paratyphoid, influenza, dysentery and malaria, shows that these particular morbid changes are not found. The writer also points out the fact that the five cases of typhoid offered unusual features in the symptomatology. He concludes with some general considerations on the lesions studied.

The Effects of Human and Cow's Milk on Unstriped Muscle.—O. B. Meyer has experimented this question by placing bits of artery in milk at the body temperature and graphically inscribing the contractions which result. These are energetic, more so in cows' than in human milk. They are from three to ten times greater in the former. This action cannot be attributed to the adrenaline which might be contained in the milk, neither is it due to the vitamines. The monophosphate of potassium and calcium oxide are above all in play, as well, perhaps, as some other salts. Sugar of milk also has part in the action, likewise the dialysants present in milk. By dialyzing cow's milk up to a certain point a milk is obtained whose curve is exactly the same as human milk as far as its action is concerned. The writer proposes to take these experiments as a basis for obtaining a dialyzed sugared cow's milk whose effects on the infantile organism would be similar to human milk.

The Etiology of Appendicitis.—Selberg, contrary to certain writers, believes that appendicitis has not decreased either in frequency or in gravity since the war. The war alimentation seems rather to have increased the number of cases. The infectious estival enteritides bring about an increase of appendicitis.

The Hemolytic Action of the Gas Bacillus.—E. Fraenkel describes a syndrome that he observed in some cases of gas edema produced by the bacillus which bears his name. This syndrome consisted of an icterocyanotic color of the skin, accompanied by a red or bluish tint of the urine. Evidently the syndrome resulted from some deleterious action on the hemoglobin. The phenomenon described by Fraenkel appears to have escaped the notice of the profession up to the present. The writer has met with three cases which developed in most peculiar circumstances. On account of pneumonia these three patients were given injections of caffeine. The edema commenced at the spot where the needle had been inserted and death rapidly ensued. The serum of the three patients was bright red and in two of the cases methemoglobin or hematin could be demonstrated. The urine contained ether hemoglobin or its derivatives. Bacteriological examination showed that in all three cases the process was a septicemia produced by Fraenkel's bacillus in pure culture. The writer asks why this action on the blood has not been observed more frequently in the innumerable cases of gas edema met with during the war. He believes that this action takes place only in an organism already attacked by some other bacterium by which the blood has been prepared for the action of Fraenkel's bacillus. Such an influence might be especially attributed to certain agents of influenzal pneumonia, such as the hemolytic streptococcus and the *Diplococcus lanceolatus*.

Dietetic and Drug Treatment of Cardiac Hydropsy.—H. Salomon has employed a potato or banana diet (2 pounds daily) in place of the original diet advocated by Karell. The advantages are: The suppression of the chlorides contained in the 800 c.c. of milk and the exhibition of a certain quantity of potassium. The dechloridation cure is quite as legitimate in cardiac edema as in renal dropsy, both processes usually producing the same effects, so that they can be treated by the same methods.

The Treatment of Malaria.—Nocht gives a summary of his principles of treatment of paludism and considers also some other questions related to them, such as becoming accustomed to the drug, the mode of action of quinine (this is not a direct toxic for the plasmodium), the drawbacks of quinine treatment when too intense or when uselessly prolonged. Nocht follows the treatment outlined: quinine is given for eight days in the daily quantity of one gram divided into three, four or even five doses, then a pause of four days, then three days of quinine, next a pause of four days. This is continued for six to eight weeks at the maximum. Intramuscular or intravenous injections of quinine only do away with the digestive disturbances and are only indicated when these arise. Arsenic preparations (salvarsan, neosalvarsan, arsalyle) are to be resorted to as alternating drugs only. They are especially indicated when the young parasitic forms of the disease or febrile paroxysms occur during quinine treatment. Methylene blue and other drugs which have been proposed offer no advantages. From the viewpoint of prophylaxis, the writer is most interesting in his remarks. Prophylaxis is of value, especially from administrative and military aspects. It has the advantage of distributing the patients more uniformly, thus preventing massive and simultaneous contaminations. But the writer believes that subjects who have been given prophylactic treatment are very prone to suffer from aggravated forms of malaria and a prolongation of the disease if they eventually contract it.

Giornale di Medicina Militare.

April 1, 1919.

Researches on the Influenza Pandemic.—Castronuovo's important study ends with the following summary: An outline of the pestilence must emphasize the relative immunity of the aged and very youthful, the summer-autumn incidence, the frequency of hemorrhagic and hemolytic phenomena, the exanthematous lesions which were quite constant—papulopustules, abscesses, phlegmons—the enanthems expressed as inflamed uvula, tonsils and pharyngeal background, the high mortality, the special type of pulmonary and renal lesions, the presence of monosymptomatic types—digestive, renal—the evidences of adrenal insufficiency, the asphyctic bulbar syndrome, etc. In regard to the connection with simple grippe mild cases of the pandemic bear a certain relationship to it. The affection is air borne within a certain radius about the patient. In regard to the relative deadliness of the mild and severe types, the former is the most active in spreading the disease, and the carrier problem must also be affiliated with the mild type.

Unusual Complication of Paratyphus.—Ferrannini has found no record of a case like the following: The patient was a captain of infantry who had reached that rank by gradual promotion. In May, 1915, he was attacked with malaise and a bronchial fever and after recovery was soon stricken again, the condition suggesting a relapse of the first ailment. After a leave of 40 days he returned to duty and once more developed fever. Routine serodiagnostic tests revealed a paratyphoid infection. There were other relapses and during 1917 it was found that he had developed an organic cardiopathy, which in time led to broken compensation, and death with cerebral symptoms. Autopsy was refused. The diagnosis had been mitral insufficiency, myocarditis, myocardial degeneration, chronic nephritis and uremia.

Book Reviews.

La Prothèse Fonctionelle des Blessés de Guerre. Par le Dr. Ducroquet, chirurgien orthopédiste de l'hôpital H. de Rothschild. Preface du Pr. Aug. Broca. Prix 5 francs. Paris: Masson et Cie., 1919.

This volume comprises 233 pages and 220 illustrations. Of its twelve chapters the first four are devoted chiefly to apparatus, two to gaits, three to fractures, ankyloses and false joints and three to the muscles. Broca's preface extols the author's knowledge of apparatus and of musculo-articular physiology. Every one of the 220 illustrations is original and executed under author's directions. The almost complete absence of radiographs indicates that their teaching significance is not great.

Papers on Psycho-Analysis. By Ernest Jones, M.D., M.R.C.P. (Lond.), Co-Editor of the "International Journal of Medical Psycho-Analysis." President of the London Psycho-Analytical Society. Late Associate Professor of Psychiatry at the University of Toronto. Revised and Enlarged Edition. Price $7.00 net. New York: William Wood & Co., 1919.

The reappearance of Dr. Jones' book will be a welcome event to the psychoanalysts. Recent converts to the theory have experienced considerable difficulty in obtaining his earlier work and they will find in the volume a revised and much-enlarged presentation of his views. Jones patterns closely after Freud and rejects the variations and modifications of Jung, Adler, *et al.* A chapter has been added on "war-shock," as Jones terms the psychoneuroses caused by the war, showing how they illustrate and prove Freud's theories, in spite of the reverse view advanced by some. There is a wealth of clinical material in the book, every aspect of the psychoanalytic theory being illustrated by many apposite examples from patients. The book is divided into five parts—an exposition of some of the more important theories, a section on dreams, a collection of papers on treatment, some clinical studies, and a series of articles on the relations between psychoanalysis and pedagogy. This last-named section is extremely important, for if the psychoanalysts can demonstrate the value of their system in child-training, they have taken a long step forward. A glossary is added, with concise definitions of psychoanalytic terms, as well as many in psychiatry and neurology, for the non-medical readers. Altogether a valuable and interesting book.

Nerve Control and How to Gain It. By H. Addington Bruce, Author of "The Riddle of Personality," "Handicaps of Childhood," etc. New York: Funk & Wagnalls Co., 1918.

This little book is one of those "popular" treatises which no doubt find their audiences somewhere as they continue to be produced. The author deals in generalities, for the most part uncontestable, and ladles out advice of the "Don't worry," "Think cheerful thoughts" school. A few of the page headings are sufficiently illustrative, "Get up with a smile," "Be generous," "Dress well to be well," and "Find joy in duty."

Hughes's Nerves of the Human Body. With plates. By Chas. R. Whittaker, F.R.C.S. (Ed.), F.R.S.S., etc., Senior Demonstrator of Anatomy, Surgeon's Hall, Edinburgh; Lecturer on Biology, New School of Medicine, Edinburgh. Author of "A Manual of Surgical Anatomy," "Essentials of Surface Anatomy," etc. Second edition, revised and enlarged. Price $1.25. New York: William Wood and Co.; Edinburgh, E. and S. Livingstone, 1919.

This little book consists of about fifty pages of text and twelve plates, and contains a very condensed summary of the anatomy of the cranial nerves, the spinal nerves, and the sympathetic system. As an aid to the beginner while he is struggling with the nerves in his text-book, this volume can be recommended. It may also be of service to those who are preparing for an examination, provided they have at some previous time mastered the subject in some adequate text-book. The old terminology has been adopted in the text, but where these terms differ materially from the B. N. A. the latter have been added within brackets. The title to plate VI should be altered to "Ninth, Tenth and Eleventh Nerves"; it is many years since these nerves have been known as the "eighth pair of nerves."

Autobiography of an Androgyne. By Earl Lind ("Ralph Werther"-"Jennie June"). Edited, with introduction, by Alfred W. Herzog, Ph.B., A.M., M.D., Member of the New York and the New Jersey Bar. Editor of the Medico-Legal Journal. Price $4.00 net. New York: The Medico-Legal Journal, 1918.

This little book is the life story of a homosexual, told with a frankness but little ameliorated by the use of Latin in certain passages. The value of such a document is extremely doubtful. At any rate, in the present instance, there is much repetition of similar incidents and an entirely too lenient editing of the author's ill-concealed pride in his career.

Hygiene of the Nursery, Including the General Regimen and Feeding of Infants and Children; Massage, and the Domestic Management of the Ordinary Emergencies of Early Life. By Louis Starr, M.D., LL.D. Eighth Edition, with Twenty-six Illustrations. Price, $1.00. Philadelphia: P. Blakiston's Son & Co., 1918.

"Just as one twig is bent, the tree's inclined," is an axiom which applies more or less aptly to the rearing of children. Therefore, the hygiene of the nursery is a factor of much importance to the future of the child. Diet is a phase of children's hygiene that bulks most prominently. In the book by Dr. Louis Starr the entire subject of children's hygiene is dealt with at length, and the outstanding importance of diet is emphasized. The outcome is an instructive little work, which points out a series of excellent hygienic rules for children. The book, which is an eighth edition, may be sincerely recommended.

A Text-Book of Practical Therapeutics, with Especial Reference to the Application of Remedial Measures to Disease and Their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., B.Sc., Professor of Therapeutics, Materia Medica, and Diagnosis in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital; one-time Clinical Professor of Diseases of Children in the University of Pennsylvania; Surgeon U.S.N.R.F. Seventeenth edition; enlarged, thoroughly revised and largely rewritten. Illustrated with 145 engravings and 6 plates. Price $5.50. Philadelphia and New York, Lea & Febiger, 1918.

Hare's Therapeutics is almost a medical household word, and becomes better with age. However, the opening remarks of the author are absolutely true that the preparation of the seventeenth edition of a book, although few writers are called upon to bring out a seventeenth edition, requires more care and judgment than the writing of the first, if it be desired to have things represented as they are and not as they have been. The winnowing of the wheat from the chaff in medical therapeutics is by no means an easy task and involves care, discretion, and the possession of a wide knowledge in the field. Dr. Hare has displayed rare acumen, and while discarding that which has been proven of little or no use, has not allowed the somewhat national desire to bow to the new to carry him to such an extent as to neglect the old simply because it is old. As he points out in the preface, the endorsement of long experience on the part of his fellows and himself is a sufficient guarantee of worth. Moreover, the author takes a broad view of therapeutic measures and does not regard askance all remedies simply because they have not been sealed with the approval of the entire medical profession. The book has been thoroughly revised and the point is emphasized that many important drugs heretofore made in Germany, or under German patents, are now made in this country, and have been given names whereby they may be properly designated, as, for example, arsephenamine for salvarsan, and procaine for novocaine. These changes have been included in the volume. Dr. Hare is to be congratulated upon bringing out the seventeenth edition of his Therapeutics and of not only equalling the high standard set by former editions but of surpassing it.

Seventieth Annual Session, Held in Atlantic City, June 9, 10, 11, 12, and 13, 1919.

(Special Report to the MEDICAL RECORD.)

SECTION ON DISEASES OF CHILDREN.

Second Day—Thursday, June 12.

(*Continued from Vol. 95, p. 1119.*)

Lung Abscess in Children.—Drs. HERMAN SCHWARTZ and HARRY WESSLER of New York presented this paper which was read by Dr. Schwartz. It gave their experience with lung abscesses in children at the Mount Sinai Hospital, where they had had 110 or 115 cases, of which 16 occurred in children between the ages of four and fourteen years of age. His observations led him to believe that lung abscesses in children were somewhat similar to those seen in adults. In a general way two types of conditions leading to suppuration in the lung might be distinguished: (1) those due to pneumonia and (2) those due to the aspiration of a foreign body or septic material during an operation on the tonsils or upper respiratory tract. It was important to make this distinction in order to draw attention to that type of lung abscesses which developed about three weeks after tonsillectomy. He believed that these abscesses were due to the aspiration of infected material from the crypts of the tonsil, which caused a local bronchitis; then later the wall of the bronchus became necrotic, broke down, and as a consequence there followed a widespread pneumonic abscess. The existence of such an aoscess might not give signs until some weeks after the operation. In some of these cases the patient after a time coughed up exudate and the cavity automatically obliterated itself, while in other cases the cavity continued to contain fluid and septic material which was a constant menace to the patient. The other type of abscess, following a pneumonia, was a chronic indurated pneumonic abscess, which might show itself as a diffuse bronchitis with profuse expectoration. The postoperative lung abscess was usually gangrenous, due to an anaerobic infection, and was frequently daily diagnosticated by the odor. It might lead to a chronic suppurative condition lasting several years. Of the 16 cases of lung abscess in children, seven followed pneumonia, six followed tonsillectomy, and three were due to the aspiration of a foreign body, one occurring after immersion in water. Those cases following pneumonia came into the hospital at periods varying from seven months to four years after the primary pneumonia, while those following tonsillectomy came in during the first three weeks or one month following the operation. The aspiration cases came in a little later. In the postpneumonia cases, the lower lobe was involved seven times and in two of these cases there was an additional upper lobe involvement. In only two of the six cases following tonsillectomy was the upper lobe involved, while in four the lower lobe was involved. About one-third of the postoperative cases recovered, so it seemed that the prognosis was much better for postoperative than for postpneumonia lung abscesses. Of 100 adult patients having postpneumonia abscess only one recovered. About one-third of the postoperative cases recovered spontaneously and several recovered after operation. He had never observed that a postoperative lung abscess was cured spontaneously if it had persisted more than three months. It was at times surprising to see the rapidity of healing in some of the postoperative abscesses. He had seen a cavity as large as a lemon heal in a week. The complications of lung abscess were very interesting and most important; chief among these was rupture of an abscess with subsequent empyema or bronchial fistula. The presence of a bronchial fistula was suspicious of lung abscess. When one found a persistent empyema or bronchial fistula, the patient should be subjected to a bronchoscopic examination as the condition might be due to the presence of a foreign body. In the presence of a lung abscess one of the first evidences to appear was clubbing of the fingers, which occurred very commonly in the earlier stages. A bronchiectasis appearing from three to six weeks after operation might disappear as rapidly as it appeared. Another complication of lung abscess was hemorrhage, which was more constant and characteristic than in tuberculosis. Very little interest attached to the physical signs as the diagnosis was dependent to a great extent on the *x*-ray findings; before undertaking any surgical procedure it was absolutely necessary to localize the lesion by means of the *x*-ray. Lobectomy seemed to be indicated in these cases.

Dr. T. C. MCCLEAVE of Oakland, Cal., said that during the period covered by Dr. Hess's report he had not seen any children, but he had seen young adults in camps. The most striking thing to his mind was the multiplicity of complications and the multiplicity of complications in the individual case. The most serious complications were of the streptococcus type or the hemolytic streptococcus infections. He cited several instances of abscess of the psoas muscle in which hemolytic streptococcus was found.

Dr. WILLIAM WESTON of Columbia, S. C., spoke of the cases of persistent consolidation of the lung in which the von Pirquet test was negative which were first brought to his attention at the beginning of the influenza epidemic. Another point he mentioned was with reference to cyanosis in cases of pneumonia following influenza. At Camp Benjamin Franklin most of the cases showed cyanosis. At Camp Jackson he saw pneumonias of Type I and II and no cyanosis. The infections with the staphylococcus gave physical signs exactly like miliary tuberculosis.

Dr. H. M. MCCLANAHAN of Omaha said that of 20 infants in the hospital with influenza pneumonia, two developed empyema and both recovered after operation. A third case which they thought was an interlobular abscess recovered. There were two cases in which they could not find any physical signs of pneumonia except as proved by the *x*-ray. Another point of interest was that five developed furunculosis. It was noted that all the cases that had a severe epistaxis did not have pneumonia. They decided that if that was true it might be a good idea to bleed. There was one child with a hemorrhage from the ear; after the hemorrhage there was no further ear trouble and the hearing was good. They had five hundred cases of influenza in Omaha. One out of five of these developed pneumonia and one out of four of the pneumonias was fatal. All the doctors agreed that during the second wave more infants and children had the disease. As a whole children resisted the disease better than adults, especially adults between 18 and 25 years of age.

Dr. E. ZUEBLIN of Cincinnati described a case in which there was fluid in the chest which showed the Pfeiffer bacillus and he thought vaccine therapy was the procedure to follow. Later there was an abscess on the lingual tongue and five weeks later there were multiple abscesses in the left lower lobe of the lung, chiefly peribronchial in type, and the bacillus could not be found; no evidence of tuberculosis could be found. The question arose as to the primary cause of these abscesses. In regard to Dr. Schwartz's paper it might be noted that they saw aspiration pneumonia often on the right side and that was because the bronchus tipped in that direction so that a foreign particle was easily aspirated in that to the right bronchus.

Dr. ELLIS BONIME of New York called attention to the blood picture in influenza. He thought the leucopenia observed in the epidemic was the most important feature as it created a different picture to any we had heretofore noted. He had been interested in the sputum pathology and where they had found the Pfeiffer bacillus before the epidemic, but after the outbreak of the epidemic they did not find this organism. He referred to experiments in which they had been able by inoculation to produce a leucopenia. The reaction to the vaccine ran parallel to the amount of leucopenia produced.

Dr. JOHN A. FOOTE of Washington said it was rather easy to diagnose abscess of the lung after operation, but not so easy in cases that occurred after pneumonia

or whooping cough, or after the convulsive cough that occurred after influenza. Even the *x*-ray was not always conclusive. As to lobectomy, he felt that was a very radical procedure. Dr. Tewkesbury of Washington had done artificial pneumothorax in cases of abscess of the lung and reported a number of successful cases in abscesses of considerable extent.

Dr. Langley Porter of San Francisco said there were two complications common in San Francisco that Dr. Hess had not mentioned as being common in his cases. Laryngitis was a common complication with their children and also a form of painless otitis media. They had 350 cases during the first wave of the epidemic and 300 during the second. The second differed in giving a larger proportion of morbidity among children. He doubted very much whether Dr. Foote's cases that were cured by pneumothorax were deep abscesses of this kind. He also doubted the statement that the lung abscess was caused by an operation for tonsillitis. He had seen about two lung abscesses that followed tonsillectomy and he wondered if the burden of proof that these abscesses were not due to embolism rather than to inhalation was not on Dr. Schwartz's shoulders.

Dr. Louis Fischer of New York said that one important point brought out by Dr. Hess was the number of cardiac complications during the last epidemic of influenza and the number of cardiac cases dying. During the last few months he had seen more and more cardiac cases coming in. Another point was the number of kidney cases, especially pyelitis.

Dr. Hess said he had passed over many of the complications because of the lack of time to go into them. Laryngitis was very common. The otitis was interesting. In about two-thirds of the cases it was not a suppurative otitis but a serous otitis. The ear drums would rupture almost while you were watching them and would heal readily. There was little mastoiditis. There was very little suppurative ear trouble in the first wave; the serous otitis was the type seen in the first wave. In the soldier epistaxis was very common and occurred in about 20 per cent. of the cases. Phlebotomy had been tried but with very little success. As to the kidney complications there was a type of acute nephritis with albumin and casts which cleared up in from 48 to 96 hours.

Dr. Herman Schwartz of New York said that in regard to the pneumothorax it was distinctly harmful and the surgeons were opposed to it. If one saw after lobectomy the thickened lung about the abscess he realized that pneumothorax was not effective in exerting much pressure. As to the question of embolism being the cause of the abscess, if embolism was the cause one would expect the abscess to occur sooner after the operation than it did. One would expect an abscess from embolism to show itself in five or six days after operation and to be ushered in by a stormy onset.

Third Day—Friday, June 13.

Dr. Franklin P. Gengenbach in the Chair.

Some Clinical Experiences in the Treatment of Children with Tuberculin.—Dr. Richard Cole Newton of Montclair N. J., presented this communication, in which he advocated the use of tuberculin as a routine diagnostic measure for the detection of tuberculosis in weak and anemic children. If a positive response to tuberculin was elicited treatment with tuberculin should follow. He reported in detail seven cases of tuberculosis in children which had shown surprising improvement under treatment with small doses of tuberculin. In summarizing he emphasized the point that there was no average dose of tuberculin, but that the dosage must be determined in each individual case. He did not agree with those who said tuberculin should not be used in the treatment of tuberculous children on account of its psychological effect. Tuberculous children should be treated not only with tuberculin, but by all hygienic measures, since the elimination of tuberculosis among the adult population depended upon its early recognition and elimination among children. The general practitioner had not learned to use tuberculin. In his experience it had worked well in every incipient case of tuberculosis in which he had used it.

Dr. Francis M. Pottenger of Los Angeles said that his conception of what went on in the child, so far as tuberculosis was concerned, was that soon after birth infection occurred, and then what happened next depended upon the amount of dosage of the infection and the resistance of the child. If the dosage was small and the resistance good, all that happened was an increased resistance to tuberculous infection. If, on the other hand, the dosage was large, an acute condition nearly always resulted, with death. If there was a moderate dose of the infection and the resistance was not good, the disease made some headway and then might quiet down, to break out a little later. In children in whom there was a gradual loss of resistance, weakness, and undernourishment, and in whom the nervous balance was unstable, it might be well to bear in mind the possibility that tuberculin might be of value. In the treatment of such children he employed the usual hygienic measures, but did not take them out of school, as he tried not to make invalids of children if it could be avoided. In this group of children he always used tuberculin. As a rule, children responded to tuberculin better before puberty than after. If one could treat these children when they were eight or nine years of age one usually got good results. If children of this type were taken in time a large part of the tuberculosis seen later in life could be avoided.

Dr. Ellis Bonhime of New York said that in regard to tuberculosis there was the advantage that 90 per cent. of the human race was immune, and that even in families in which some of the members had died of tuberculosis other members might be immune. Children of tuberculous families should be given the von Pirquet test once in six months, and if at any time they gave a positive reaction a course of tuberculin treatment was absolutely indicated. He had not seen a case of tuberculosis develop in any case in which this course was followed, even in families in which there was an extensive history of tuberculosis.

Dr. Fritz B. Talbot of Boston expressed the opinion that the trend of this discussion was rather dangerous. His experience did not uphold any absolute evidence of the beneficial effects of tuberculin treatment in children. All children susceptible to tuberculosis might be treated by other means—fresh air, good food, rest, and sunlight—and it seemed to him that some of the cures attributed to tuberculin might be due to these hygienic measures. There was a dangerous element in giving tuberculin because every one admitted that the dosage was a very important factor in determining infection or disease, and the younger the child the more easily would a tuberculous infection become a tuberculous disease. Personally, he thought there was danger that the tuberculin might awaken an infection into an active tuberculosis. If the claims that were being made for sunlight were substantiated, he thought it would be just as effective and much safer than tuberculin.

Dr. Abraham Levinson of Chicago emphasized the danger of tuberculin in pulmonary tuberculosis, and said that even if tuberculin were beneficial in glandular tuberculosis in children one could not be sure that there was not a primary focus in the lung and a secondary glandular involvement. He had seen one or two cases in which he believed tuberculin was responsible for a miliary tuberculosis. It was well not to be carried away by enthusiasm for tuberculin, and to remember that even though tuberculosis in a child was glandular there might be a latent pulmonary focus that could be lighted up by tuberculin.

Dr. Newton, in closing, compared the timidity of physicians in reference to the use of tuberculin to the opposition to diphtheria antitoxin when that remedy was first used. He urged physicians to learn more about the proper use of tuberculin and give it a trial without fear and without prejudice.

Dr. Pottenger of Los Angeles said he had treated thousands of adults and hundreds of children with tuberculin, and he had never seen a case of meningitis started by tuberculin such as was referred to by one of the men who discussed the paper.

Recent Developments in Outpatient Work.—Dr. Charles Hendee Smith of New York presented this communication, in which he said nearly every hospital was divided into wards and an outpatient department,

the wards under the older and more experienced men and the outpatient department under the younger men, and that between the wards and the outpatient department there was only a nominal connection. As a result of this arrangement there was a very bad manning of the outpatient department and the patients received poor treatment. The outpatient department should be coordinate with the wards in every pediatric service, because the outpatient department of a pediatric service had a very important work. Only the acute diseases or conditions of children were treated in the wards; chronic conditions were not much influenced by their stay in the wards, because the children were in an unnatural environment that was not favorable to good results in this class of cases. It was beginning to be recognized that a properly conducted outpatient department offered a better way of treating these chronic conditions. A close connection between the wards of the hospital and the outpatient department should be maintained. The organization of the Bellevue Hospital Children's Service was based on this plan. The close connection of the wards and the outpatient department was effected by having the members of the staff working in both departments. The internes also had duties to perform in connection with both departments. Dr. Smith described in detail the way in which the duties of the wards and outpatient departments were divided between the physicians of the ward staff and the internes, and emphasized the advantage that this plan afforded as a means of giving instruction to the internes and other physicians desiring to study pediatrics. He described the printed history forms, diet lists, and methods of keeping all data, and stated that the volunteer system of clinical assistants had worked very well at Bellevue. They had found it an advantage to adopt the class system in the management of these patients. They had a cardiac class, a nutrition class, syphilis class, infant feeding class, etc. This method was valuable because it aroused a spirit of competition among the members of a class as to which could progress most rapidly; it saved time because instruction could be given to the children and their parents and guardians in groups instead of individually, and it gave the physician the advantage of being able to make comparative observations. In speaking of the educational value of such a service, Dr. Smith said they were now taking men who wished to work in such a service. Many men coming back from military service were taking a course of a few weeks with them. They trained the internes to handle mothers and children and to educate the mothers in hygiene. They were teaching the physician when he saw a child not to ask himself how quickly he could get rid of it, but how much he could do for it, and to regard the education of the mother and child in health habits as an essential part of his duty.

Dr. JOHN LOVETT MORSE of Boston said they were doing practically the same thing in Boston as Dr. Smith was doing, except that they did not have printed forms for histories, and he felt that the use of a printed form made history taking mechanical. The printed form of instructions was all right for the mother but not for the doctor. He said that he took the service in the outpatient department himself for a time every year.

Dr. ISAAC ABT of Chicago said he thought Dr. Smith's paper had a very far-reaching significance that might not be appreciated if one only looked at it superficially. It was the sign of a new era. It emphasized the question of the social relations, duties, and obligations of the physician to the patient, not only the sick patient, but the child that was brought to him as well. This paper brought to all of them the fact that the dispensary should be organized in this way. It emphasized that a great deal could be done by educating not only the little patient, but the father and the mother and the whole community. He understood that Dr. Smith not only had one of the best organized dispensaries in the country, but that he had a reputation of treating all his patients with the utmost kindness and human sympathy, a trait they all should emulate.

Dr. LANGLEY PORTER of San Francisco said it was a reflection on the profession that only a dispensary class could have a children's service such as had been described. Aside from the poor visiting the dispensary, only the wealth could have these advantages. He thought some plan should be devised by which people in moderate circumstances, by the payment of a small fee, could have the benefit of the class work along lines similar to that Dr. Smith had described. He thought that work should be followed as a guide in private practise in many respects.

Dr. SMITH, in closing, urged Dr. Morse to try the printed forms for history taking and assured him that they did not have the effect of stopping initiative in the doctors. He had heard a number of men express the same opinion as Dr. Morse had done, but without exception they came to recognize the value of the printed form. The fact was the printed form got the history and the blank form did not or if it did get it, the history was apt to be unsystematic, rambling, and unsatisfactory.

Retrospect of Fifteen Years in the Treatment of Hypertrophic Pyloric Obstruction in Infants.—Dr. LANGLEY PORTER of San Francisco presented this paper, in which he reviewed the earlier views of Hutchison on the sufficiency of medical treatment in hypertrophic pyloric obstruction. However, all physicians were not as successful with medical treatment as Hutchison and the opinion became general that medical treatment was inefficient. In the early 90's they began to cast around for a more satisfactory method of treating these cases. Pyloroplasty and gastroenterostomy were suggested and tried. Fredet devised an operation quite similar to that of Rammstedt. He reported only one case, however, and the method was allowed to lapse. Several series of cases were presented showing the writer's results with the different methods. Of seventeen cases operated on by gastroenterostomy, five died and twelve recovered. It seemed at the time these operations were done that unquestionably the results of gastroenterostomy were better than those of medical treatment by the Hutchinson method. It was for a long time a difficult problem to know what to do with these cases. In 1915, the writer saw Dr. Holt's cases operated on by Dr. Downs by the Rammstedt method. He objected to this name and insisted that the credit should be given to Fredet, and the operation called the Fredet or Fredet-Rammstedt operation. His experience with this operation was confined to twenty-six cases, of which two died and twenty-four recovered. The two cases that ended fatally died of conditions having nothing to do with the operation, so that this series gave practically 100 per cent. of cures. Of these cases eighteen were performed by one surgeon in California. The Fredet-Rammstedt operation had the advantage that it was done rapidly and simply by almost anyone who had a good knowledge of surgery, and a rapid recovery followed. If the operation was properly done the child was on a normal milk formula in six or eight hours after the operation, and proceeded on its way without further trouble. A number of these children tended to regurgitate their food after operation; when that occurred the patient should sit in the erect position and the vomiting would be modified. After this experience the writer thought there was no way of dealing with these cases except by this operation. When he heard Dr. Helmholz state that these patients recovered on dietetic treatment without operation he was at first inclined to think that the type of cases which Dr. Helmholz had encountered were different from those he had been seeing but after returning home he had had an experience with a hypertonic, dried out child that had modified his views. Whether in such a child one intended to do a Fredet operation or to employ medical treatment, the first thing to do was to get fluid into the child. The most advantageous way was through the peritoneum, by giving an injection of 500 c.c. of normal saline—5 ounces of skim milk, 15 ounces of water, four tablespoonfuls of rice flour, and four tablespoonfuls of dextromaltose, made up to the amount. The child should be given also normal salt and glucose by mouth and normal saline per rectum. By starting the cases off by this treatment and then employing the method of feeding suggested by Dr. Helmholz and Dr. Sauer, he had treated ten cases with ten cures. A case of hypertrophic pyloric stenosis in an infant should be first treated by the Sauer-Helmholz method and then, if within a few days the baby did not respond, the Fredet-Rammstedt operation should be performed.

Dr. Alfred A. Straus of Chicago called attention to the fact that he was the author of the operation that bore the name of Rammstedt and that he had reported three cases before Rammstedt reported his case. He explained that in doing the operation he did a little more than Rammstedt had done in that he partially shelled out the thickened portion and then brought the walls together so that the wall was completely closed by muscle. He had done 142 operations of this kind, with three deaths, one of these fatal cases being moribund when operated on, one died of pulmonary embolism, and the third had atresia of the intestinal tract. The mortality of the Rammstedt operation was from 10 to 20 per cent.; the mortality with his operation was 3 per cent. The rule by which he decided which cases required operation was to fluoroscope the child, and if 80 to 90 per cent. of the food passed through the pylorus in two hours the case was not operated upon; if the food was retained for four house or longer, operation was indicated.

Dr. Henry F. Helmholz of Chicago said that he was still continuing to use the medical treatment he had recommended. They had their failures, however. The method was never put out as a panacea for pyloric stenosis. As to Dr. Straus' procedure for deciding upon the advisability of operation, that should be modified, because it would be found that an ordinary milk mixture might be followed by a 100 per cent. retention, while if cereal were added to it the entire amount would pass through the pylorus in four hours. He asked Dr. Porter if he had seen any cases of pyloric obstruction in children operated under local anesthetic.

Dr. Harry Lowenberg of Philadelphia said he thought it was better to stop speaking of spasm and hypertrophy, and to classify the cases as surgical and nonsurgical. The surgical cases might be divided into complete and incomplete, and the nonsurgical were simply incomplete. While the *x*-ray was valuable one should not be entirely guided by it, but should be guided by the weight of the child and the character and size of the bowel movement. He suggested giving charcoal and then seeing how much was found in the stools and how much recovered from the stomach by lavage. He was not in accord with the view that anybody could operate on a case of hypertrophic pyloric obstruction in an infant; he thought only a man should operate who was accustomed to handling the intestines of a young child.

Dr. Julius P. Sedgewick of Minneapolis said he wished to support the position of Dr. Porter and Dr. Helmholz. He had a series of sixty-eight cases, sixty-four of which were treated medically without a death. Other physicians had seen many of these cases and agreed with him that they were cases of hypertrophic pyloric obstruction. He thought that one could cure more cases by medicine than by surgical means, but it took longer and was a tiresome procedure to carry out a proper course of medical treatment. They had used Dr. Helmholz's method and found it valuable.

Dr. Fritz B. Talbot of Boston said that if one was going to select a method and use it to the limit, it was not fair to the surgeon to use the medical method first and then, when that had failed, to hand the child over to the surgeon. If the surgeon was to succeed he must have the baby first.

Dr. Laurence R. DeBuys of New Orleans said that if the obstruction was complete the baby should be operated on immediately; if the obstruction was partial, the weight curve should be the guide.

Dr. Porter, in concluding, said he had no disagreement with Dr. Talbot; his idea was to take fewer babies to the surgeon and get better results. He apologized for having overlooked the work of Dr. Straus and he thought Dr. Straus had overlooked the work of Fredet. He had had no experience with the shelling out method, but he had seen the omentum closed over the incision by Nature in much the same way as Dr. Straus said he did it. Local anesthesia was indicated in children that were poor surgical risks.

Chemical Examination of the Blood of Children.—Dr. Henry Dwight Chapin of New York presented this communication, which was based on the blood examinations made in 138 miscellaneous cases of infants and children, among which were thirty-eight cases of nephritis and six of diabetes. The sugar, urea, urea nitrogen, creatinin, carbon dioxide combining power, and the phthalein output were estimated. The blood examinations were in cases of chronic nephritis, chronic nephritis following acute infection, and a number of miscellaneous conditions. The normal figures for sugar, urea, urea nitrogen, and creatinin in the blood in children differed little from the normal figures for adults. The blood of children showed a better phthalein output. Nephritis in children did not result in urea retention so quickly as in adults. Creatinin rarely occurred, though it was found in two of four cases dying of chronic interstitial nephritis. The blood urea was an especially helpful diagnostic test in nephritis of children. The results of the phthalein test harmonized well with the clinical findings and the blood urea. The carbondioxide combining power of the blood was a very reliable method of ascertaining the severity of the acidosis. In a series of diabetic cases the changes in the blood antedated other symptoms. One frequently found a hyperglycemia before a glycosuria was detected. The findings in diabetic children did not differ from those found in adults.

The Abuse of Catharsis and Laxatives in Infancy and Childhood.—Dr. Louis Fischer of New York read this paper. He said the daily administration of laxatives and correctives to infants and children was a common practice among many mothers and nurses. This was well known to most physicians. Indiscriminate drugging to cleanse the intestine and empty the liver was a daily routine, and this abuse was founded on the enormous amount of advertising matter which convinced the laity of the necessity of so doing. This practice was so common that it was rare to hear of children whose bowels functionated normally. Drugs and correctives were used without rhyme or reason to suit the whims or ideas of the person in charge of the infant. It was not an exaggeration to speak of this as an abuse of catharsis in children. While the daily use of drugs might be required for a short time to stimulate the secretions and cleanse the gastrointestinal tract, it was unnecessary to continue this practice over a period of many months. In acute febrile manifestations or in toxic and septic conditions where sluggish or pseudoparalytic functions existed, laxatives were indicated and were urgently required to eliminate stagnant residue and fermenting particles of food and their toxins which might be absorbed into the circulation. This was especially true in intestinal intoxication accompanied by fever, caused by excessive fat or protein feeding. In this class of cases the subnormal condition caused by the fever demanded especial attention. It was our duty as physicians to sound a note of warning to the laity that the pernicious habit of giving a daily laxative lessened the functional activity and weakened the intestinal mucosa. This would in time result in a total loss of the peristaltic waves, whereas modifying the diet and adapting it to the child would modify the same. Peristalsis could be stimulated and aided in many ways other than by drugs, and it was because of the large number of infants who daily received a cathartic dose of medicine that he was urged to invite your attention to this subject. While we might attain the object of cleansing and eliminating fecal particles, we frequently interfered with the normal process of digestion and assimilation and deprived the system of nutrition intended for growth. He believed that the excessive purgation weakened the glandular functions and robbed the system of ferments and enzymes necessary for the proper assimilation of food and thus indirectly invited rickets and weakened structures due to faulty metabolism. Rachitic atony of the musculature simulated constipation. The stagnant fecal contents could only be propelled by stimulation of the gut and restoring the needed tone. It was in this class of cases that cod liver oil was so efficacious. The well-known results of thyroid therapy in sporadic cretinism and the specific action on the constipation accompanying this disease needed no emphasis from him. The administration of ¼ grain thyroid, three times a day, gradually increasing the dose until one grain was given three times a day, had acted beneficially in quite a number of cases. The daily administration of a warm soap water enema should also be condemned. The warm water relaxed the muscles of the intestines, and if persisted in would

produce an atony of the intestines with a tendency to prolapse. A cold enema (60 to 70° F.) had a stimulating and tonic effect. Not more than one pint was given at bedtime, or before the second morning feeding. The importance of water in the diet was not sufficiently emphasized. Fresh, cool water would aid in eliminating food residue if given between meals, several times a day. Water added to the food was not sufficient. For the older child the mechanical stimulus in the atonic gut could be given by the addition of bran to cereals or by the use of figs, raisins, whole wheat bread, and the coarse cereals such as oatmeal. Vegetables such as chopped spinach or string beans—the green vegetables rather than the starchy cereals such as potato—should be given.

Dr. JOHN LOVETT MORSE said that cod liver oil and prune juice had no antiscorbutic properties, though both were thought to possess this property. If he gave three-quarters of a grain of thyroid to a child without getting a reaction he would be inclined to think he had made a mistake and that he was dealing with a case of cretinism. A normal child usually reacted to that dose.

Dr. LAURENCE R. DEBUYS called attention to the fact that these cases of constipation frequently had their incipience in the first few days of life. If doctors and nurses would not interfere with nature at that time there would be fewer cases of constipation later in life.

Dr. FRED H. ALLEN of Holyoke, Mass., said it should be borne in mind that breast-fed babies were also constipated at times. If the mother were given proper instructions for the control of her own constipation in regard to diet and exercise that might solve the problem for the breast-fed infant.

Dr. ISAAC ABT of Chicago recommended vegetable laxatives if a laxative was really necessary instead of castor oil or magnesium sulphate, since they did not have such an irritating effect on the intestinal tract.

An Analysis of Human Milk: The Technique of Obtaining Samples and the Interpretation of Results.—Dr. FRITZ B. TALBOT of Boston presented this communication which was based on the analysis of a large series of human milks. He was inspired to undertake this work because of the lack of knowledge of the chemistry of human milk, by the consideration that Dr. Sedgewick and others had given this subject, and partly by the new method of analysis evolved by Folin and Dennis. The analyses had shown that there were certain enormous changes in the milk. Its composition varied from the beginning to the end of lactation and from the beginning of nursing to the end of nursing. This fact was of great importance in getting samples. The first milk drawn contained a lower amount of fat and the last contained a high percentage of fat. The difference in the amount of fat in the two periods might be as much as ten per cent. In the second place there was a difference in the amount of lactose from the beginning to the end of nursing. The lactose content was higher at the beginning than at the end of nursing. The difference was not as great as in the fat, being rarely more than one per cent. The difference in the percentage of protein in milk drawn at the beginning and at the end of nursing was so little that it could be neglected. Hence to get an accurate analysis of the milk in a given case a specimen must be taken after the mother had nursed the baby and mixed with a specimen taken before nursing, or else an analysis should be made of the composition of both specimens and the results averaged. Another question of great importance was the method of analysis. The lactometer and ordinary methods were inadequate. Another point which he had brought out in his discussion of the previous day was that before one was capable of judging whether or not a milk was abnormal he must know whether it was normal or not. There were normal variations in the amount of fat ranging between 2 and 8 per cent. The normal variation in the amount of sugar was from 6 to 8 per cent. Milk might contain in the early days of lactation 2½ per cent. of protein and at the end of ten weeks only 1½ per cent. protein. After ten weeks it was below 1 per cent. As to the question "How can the chemical analysis of human milk be of value," that might be best answered by citing instances in which there was marked indigestion in a baby and all other factors had been ruled out. In this case the mother's milk contained fat, 1 per cent.; lactose, 8 per cent., and protein, 1 per cent. When that baby was put on the bottle it did well. That was an isolated instance. Other instances were cited showing such wide variations from the normal that weaning was indicated. In closing, Dr. Talbot again emphasized the necessity of knowing the normal limits of variation in order to avoid serious mistakes, otherwise a normal milk might be thought to be abnormal and a baby weaned when there was no necessity for so doing.

Dr. JOHN A. FOOTE of Washington brought out the point that there might be a variation in breast milk during different periods of the day. The composition of the milk in the morning would not be the same as in the afternoon. The analysis of only two or three specimens done in the routine way would lead a man astray oftener than in the right direction.

Dr. TALBOT, in closing, said that the appearance of the milk was no guide as to the chemical composition. He had seen a rich yellow looking milk contain only 0.9 per cent. fat.

The Nervous Child and His Management.—Dr. E. BOSWORTH MCCREADY of Pittsburgh presented this paper, in which he made the statement that nervous inadequacy was the rule rather than the exception in modern life. Nervous stability of the adult was dependent on hereditary endowment and on the stimulative forces of nature and nurture. The modern home was often conducted with no thought of furnishing a suitable environment for the child. Nervous instability occurred as a result of (1) hereditary deficiency in developmental forces; (2) hereditary deficiency aggravated by inadequate stimulus through nurture; (3) malign factors in the environment affecting an hereditarily sound constitution in which the stimulative developmental forces were adequate, or in which there existed an insufficiency or perversion of stimulative forces. Early childhood was the time for the institution of corrective measures. Corrective measures should aim to stimulate developmental forces and to remove or counteract malign factors in the environment. Such measures might be broadly grouped under medical, hygienic, and educational. Tonics, alteratives, and organic preparations were of value in medical treatment. In outlining a plan of treatment for the nervous child he stated that first a proper environment must be secured; to gain this end it was often necessary to remove the child from his customary environment. A large percentage of children in well-to-do homes were undernourished. One of the first essentials in the treatment of the nervous child was to see that he had a properly balanced ration and was receiving a sufficient quantity of food. Other essentials were exercise and fresh air. Life in a modern apartment was a pest for anyone and an abomination for the child. He advocated the return to a fairly primitive form of life. Seguin had said many years ago that they should teach nothing from textbooks that could be learned from Nature, nothing indoors that could be learned from Nature, and nothing from dead Nature that could be learned from living Nature. The time would come when that plan would be carried out with the modifications necessary to meet the needs of the time. Garden schools and fresh air schools were a step in that direction and the results already demonstrated in such schools warranted their further development.

Dr. PERCIVAL EATON of Pittsburgh made a plea for the education of the coming generation of girls in the proper rearing of children.

Dr. ROBERT W. MORSE spoke rather pessimistically of his experiences in trying to educate certain mothers. Where the parents themselves were nervous fools he thought it impossible to teach them how to bring a child up properly.

Dr. H. B. WOOD of Providence, R. I., expressed the opinion that more attention should be given to the education of the fathers. He brought out the point that the father's condition at the time of conception had an important influence on the child. Worry, overwork, and nervousness in the father had a definite effect on a child conceived at such a time.

A Study in a Foundling Institution to Determine the Existence of Congenital Syphilis.—Dr. LAURENCE R. DE BUYS, MAUDE LOESER, and FOSTER M. JOHNS of New Orleans presented this communication, based on a study

of 106 children upon whom both the Wassermann and luetic tests were made and the clinical symptoms observed. The tests were most carefully controlled and guarded against error. The children were classified as to whether they were legitimate or illegitimate. Of the children in this series 83.96 per cent. gave positive reactions, and 9.53 per cent. showed clinical findings with skin eruptions. Many other cases classified as doubtful or negative had certain of the clinical symptoms of congenital syphilis but not sufficient to warrant a positive diagnosis. The fact that some of the reactions were negative might have been explained by the drastic course of antiluetic treatment to which these children were subjecting as a routine measure or it might have been that the bloods had not yet become positive. The luetin test in this series proved of greater value as a diagnostic measure than the Wassermann reaction in detecting cases of congenital lues and the clinical findings were of greatest value at the time when the value of the luetin was at its minimum, namely, the first few months of life. The effect of the iodides upon the luetin reaction was again shown in this study. The lesion was characteristic and could not be confounded with the normal positive luetin reaction. Because of the ages of the children examined and the character of the institution this investigation afforded an excellent opportunity to study the various available means of detecting the existence of congenital lues. Of the children studied, 74.6 per cent. were under the age of two years, and of these 41.6 per cent. were below one year of age. Congenital lues was found to be relatively more frequent in the illegitimate than in the legitimate children. This series, the writer stated, did not constitute a fair criterion for a comparison of the Wassermann and luetin tests, but it did afford a good idea of the relative values in connection with congenital lues at this time of life. The existence of skin eruptions of syphilitic origin in cases in which both the Wassermann and luetin reactions were negative was of decided interest and further emphasized the necessity of employing all available means, including the complete physical examination and laboratory tests, before concluding whether ar not congenital lues was present. Enlarged liver, spleen, and glands appeared to be the most constant of the clinical evidences of congenital syphilis. It was found that doubtful reaction occurred most frequently in the younger children.

Dr. W. S. Ramsey of St. Paul referred to a paper which he read before the American Pediatric Society at the 1918 meeting in which he presented an analysis of the elimination of mercury in children. In this study a large series of children were given mercury in all sorts of ways and it was found to be absorbed very readily and very rapidly, and it was also found that they had been giving mercury in much larger doses than was necessary. Mercury in the doses given in these experiments continued to be eliminated for a period of eight or ten days. When given by the mouth the least time in which it continued to be eliminated was five or six days. The study had shown that undoubtedly mercury had been given in much larger doses than was necessary, especially in children.

Dr. J. H. McKee of Philadelphia asked if any dark field examinations had been made. It seemed to him that in many skin eruptions it would be better to make the dark field examination. In the cases he had studied there was only one instance in which the luetin test was positive where the Wassermann test failed. He stated that one Philadelphia physician had declared that he made it a practice to send a specimen of blood to five laboratories. He found that three of them were absolutely unreliable, one was sometimes right and sometimes wrong, and only one was always correct, and that was the University of Pennsylvania Laboratory.

Dr. De Buys, in closing, said the dark field examinations had not been made. He quite agreed with Dr. Ramsey that these children had been over medicated and he thought that was why so many of them were found to be under par later in life, as he had shown in a previous study. He thought the luetin test was very valuable, but the injection must be made intradermally and not subcutaneously.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Ohio State Board of Medical Examiners.

December, 1918.

(*Continued from Vol. 95, page 1036.*)

DIAGNOSIS.

1. Give differential diagnosis:—(*a*) Cholecystitis and duodenal ulcer; (*b*) appendicitis, acute, and nephrolithiasis.
2. How would you make an early diagnosis of empyema of the thorax?
3. Give clinical description of shell shock.
4. Describe as you would to court and jury—(*a*) dementia præcox; name types; (*b*) paranoia.
5. Give differential diagnosis:—Pneumonia—lobar and lobular.
6. Give differential diagnosis:—Meningitis, cerebrospinal epidemic; and meningitis, tuberculous.
7. Describe typhoid and paratyphoid fever.
8. What is a pathognomonic sign? Give a number of examples.
9. Describe—(*a*) smallpox, (*b*) chickenpox.
10. Differentiate—lymphadenitis, specific and nonspecific.

PRACTICE.

1. How would you recognize the occurrence of pneumonia complicating influenza, and outline the treatment?
2. How would you recognize acute pericarditis, and give treatment?
3. Give causes, symptoms, and the usual progress of cardiac decompensation.
4. Give the symptoms and treatment of cerebrospinal meningitis.
5. Differentiate scarlatina from measles; from simple angina.
6. Name one of the frequent and serious complications of scarlatina. At what period of the scarlatinal attack does it commonly occur, and how would you recognize its onset?
7. Describe the prophylactic treatment of tetanus, and give the character of injuries in which you would advise such measures.
8. Give symptoms and treatment of acute dysentery.
9. Give causes and symptoms of brain abscess.
10. Give some of the theories as to the causes of asthma, and outline the treatment (*a*) during attack; (*b*) between attacks.

ANSWERS.

DIAGNOSIS.

1. (*a*) In *duodenal ulcer* there will be pain in the right hypochondriac region occurring about 3 hours after meals; intestinal hemorrhages which produce tarry or red stools, and anemia.

In *cholecystitis*, the pain is in the right hypochondriac or epigastric region, and occurs in paroxysms and without reference to time of eating; nausea, vomiting and jaundice may be present; constipation is common; and there is generally severe prostration.

(*b*) *Acute appendicitis.* "When the three cardinal symptoms of the disease are present—that is, sudden onset of acute abdominal pain, followed by vomiting, occurring in one previously well; unilateral rigidity of the right lower abdominal wall; tenderness over the site of the appendix—the diagnosis of *acute appendicitis* is warranted in nearly every case."—(Deaver's *Appendicitis*)

Nephrolithiasis. Symptoms consist of pain in the loins, markedly increased by exercise, especially on jolting. The pain may be referred to the thigh, groin or testicle. The colic is associated with hematuria and often pyuria exists with frequency of micturition. The kidney may be enlarged, and tender on pressure. A large stone may exist without any symptom whatever. The most typical symptom consists in a sudden attack of excruciating and paroxysmal pain shooting down the loin to the bladder and testis. The attack is ac-

companied by vomiting, faintness, and collapse. Frequent efforts to pass urine are made, but only a scanty amount of blood-stained urine is passed. The pain ceases suddenly when the calculus slips back into the pelvis or reaches the bladder.

2. *Early diagnosis of empyema of the thorax* may be made by the (generally) sudden onset, with an acute condition, high temperature, rapid pulse, chills, loss of strength, pallor, the affected side does not move well, absence of breath sounds on affected side with diminished resonance and vocal fremitus, dulness on affected side, leucocytosis, and presence of pus (ascertained by exploratory puncture or incision).

3. *Shell-shock* is a term which has no exact significance; it is vague. Different types have been described by Dr. E. F. Buzzard, as follows:—

(1) *Pure exhaustion cases*, occurring in men who, starting with an average allowance of resisting power, after a more or less prolonged exposure to the strain of warfare, become restless, irritable, depressed, sleepless, and lacking in attention and concentration. (2) Patients who have *inherited neuropathic or psychopathic tendencies*, and in whom the process of exhaustion has excited these dormant tendencies into activity. These patients exhibit, either for the first time or in the form of a relapse, such phenomena as tics, articulatory defects, epilepsy, or phobias, or insanity. (3) *"Martial misfits,"* men who are compelled to join the army by public opinion, who may pass as normal individuals in ordinary life, but who are quite aware that they cannot stand the strain of warfare. (4) Normal healthy individuals who suffer from *concussion* as the immediate result of a too close intimacy with a shell explosion, and who react in the same way as do most patients to a severe blow on the head. The period of unconsciousness is followed by a more prolonged period, during which the patient evinces symptoms similar to those of exhaustion. He is easily tired, irritable, over-reactive to auditory and visual stimulation, lacking in confidence and concentration, and often depressed. He suffers from headache, insomnia, or fighting dreams, and in brief resembles the exhausted patients referred to above. (From *The Lancet*, Dec. 30, 1916.)

4. *Dementia præcox* "is a general name given to several forms of constitutional psychoses which appear usually before adolescence is complete. It is characterized by progressive psychic exhaustion and tendency to dementia, while in its course there develop mental excitement, motor disorders, and delusional and stuporous states. It runs a long course with remissions, and it is usually three or more years before decided dementia occurs. Rarely the progress is arrested and cure takes place. The types described are the simple or hebephrenic, katatonic, and paranoid." (Dana's *Nervous Diseases and Psychiatry.*)

Paranoia "is a chronic psychosis, characterized by the development gradually and soon after maturity of systematized delusions, without other serious disturbances of the mind and without much tendency to dementia." (Dana's *Nervous Diseases and Psychiatry*).

EPIDEMIC CEREBROSPINAL MENINGITIS	TUBERCULOUS MENINGITIS
Onset: Sudden, with few prodromes.	Longer prodromes; family history; other evidences of tuberculosis.
Fever: Fairly high; pulse more rapid.	Less; inversed type frequent.
Eruptions: Herpes and purpura very common.	Rare.
Leukocytosis: Regular and marked.	Exceptional.
Rigidity of neck: Most frequent.	Spinal symptoms less frequent.
Other symptoms: Peptonuria.	Choroidal tubercles.
Course: Rapid—more recoveries.	Subacute, slower, fatal.
Lumbar puncture: Meningococcus; leucocytes, polymorphonuclear.	Tubercle bacilli; mononuclear.

—(Edwards' *Practice of Medicine.*)

7. *Typhoid fever* is an acute, infectious, febrile affection, due to a special poison (the bacillus typhosus); characterized by insidious prodromes, epistaxis, dull headache followed by stupor and delirium, red tongue, becoming dry, brown, and cracked, abdominal tenderness, early diarrhea and tympany, and a peculiar eruption upon the abdomen; rapid prostration and slow convalescence; a constant lesion of Peyer's patches, the mesenteric glands, and the spleen with enlargement of the latter. The temperature chart is characteristic.

Paratyphoid fever is an infectious fever produced by a special bacillus, intermediate between the typhoid and colon form, called the paratyphoid bacillus, and possessing clinical features similar to those of typhoid, but of milder type. Diarrhea and termination of fever by crisis are more common than in typhoid. There are no characteristic lesions. Intestinal ulceration is never present. Purulent arthritis and myositis may occur as complications in this disease, but are very infrequent in typhoid. The blood serum in this disease gives an agglutination reaction with fresh cultures of the paratyphoid bacillus, but not with typhoid cultures. The diazo-reaction is generally positive. The outlook is more favorable than in typhoid fever, and the treatment is the same. (Hughes' *Practice of Medicine.*)

8. *Pathognomonic signs* are such as absolutely indicate the presence of a certain disease or condition. *Examples* are: Koplik's spots in measles; hearing the fetal heart sound in pregnancy; finding the specific microorganisms in the fluids, tissues, or excretions in the infectious diseases; diminished hemoglobin in chlorosis; greatly diminished number of red cells, with nucleated red cells, in pernicious anemia; the presence of myelocytes in the blood, in spleno-medullary leukemia.

9. In *smallpox:* The eruption usually appears first on the forehead and wrists, and on the third or fourth day; it is first macular, then papular, then vesicular, and finally pustular; it does not appear in successive crops; the spots are multilocular, and do not collapse on being punctured; the papule is hard and shotty, and does not disappear on stretching the skin. In *chickenpox:* The eruption usually appears first on the trunk, is evident on the first day, comes in successive crops, is not shotty, and disappears on stretching the skin; the spots are unilocular, and collapse on being punctured.

Smallpox is an acute epidemic and contagious disease; characterized by severe lumbar pains, vomiting, and an initial fever, lasting from three to four days, followed by an eruption which passes through the stages of macule, papule, vesicle, and pustule; the development of the pustule being accompanied by a secondary fever during the presence of which grave complications are prone to occur.

Chickenpox is a mild, contagious, febrile affection; characterized by a moderate fever and the appearance of a vesicular eruption which dries up and falls off in from three to five days. Its cause is unknown Children are most often attacked. (Hughes' *Practice.*)

5. LOBAR PNEUMONIA	LOBULAR PNEUMONIA
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct, and there is a large area of consolidation.	Physical signs indistinct, and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

10. LYMPHADENITIS. "In *chronic simple lymphadenitis* some source of continuous irritation in the area drained by the lymph glands may be discovered. Although the glands are enlarged and perhaps tender, they do not tend to mat together or to suppurate. Removal of the source of irritation results in cure. If recovery does not follow appropriate treatment, a strong suspicion of tuberculosis should be entertained. *Tuberculous lymphadenitis* progresses despite local treatment, and successively involves gland after gland. The glands show a strong tendency to adhere to each other and to the skin, and to undergo caseous degeneration. The condition is most common in children, in whom other signs of tuberculosis may be recognized. The family history is of some importance. *Syphilitic lymphadenitis* is diagnosticated by the history of a sore, by associated lesions of syphilis, by the Wasserman test, and by the results of treatment. The glands are hard, discrete, not adherent to each other or to the skin, do not tend to suppurate, and are neither painful nor tender. The enlargement in the primary stage is confined to the glands anatomically related to the sore; during the secondary period the distribution is general, the epitrochlear and post-cervical glands always being involved; in the tertiary period the glands may become gummatous, the diagnosis then resting upon the history and the results of treatment." (Stewart's *Manual of Surgery.*)

PRACTICE.

1. LOBAR PNEUMONIA: "*The first stage* is characterized by sudden onset with chill, a sharp pain in the side, rise of temperature, a short and sharp cough, rusty-colored, viscid sputum, and dyspnea. There may be headache, insomnia, scanty urine with diminution of urea, chlorides, phosphates and sulphates, insomnia, and herpetic vesicles on the face, and there is always an increase in the number of leucocytes in the blood. Physical examination will reveal diminished expansion, impairment of the normal percussion note, feeble or suppressed respiratory murmur, moist or dry râles, crepitation, and sometimes a pleural friction sound.

Treatment: "Consists in rest in bed, milk diet, and the administration of fractional doses of calomel followed by a saline in the early stage. The nervous symptoms and temperature may be controlled by applying ice-bags or compresses wrung out of cold water (60° to 70° Fahr.) to the chest or by the use of the warm or cold wet-pack. The heart and pulse should be sustained by the administration of alcohol, strychnine (gr. 1/60 to 1/20), atropine, caffeine, strophanthus, and nitroglycerin. Digitalis may also be employed. Inhalations of oxygen afford temporary relief when the dyspnea and cyanosis are extreme. In young, vigorous, and plethoric adults, with hyperpyrexia and a high-tension pulse, bleeding may be beneficial in the first 48 hours. Convalescence should be guarded, and tonics, stimulants, etc., will be found very useful in this period of the disease." (*Pocket Cyclopedia.*)

2. *Pericarditis.*—The symptoms are somewhat obscure and may be masked by previously existing disease. Taking a typical case as it occurs in the course of rheumatic fever, we usually find precordial distress; sharp pain is rare, but when present it is most marked at the lower end of the sternum. Moderate fever, or exacerbation of already existing fever, at the onset; dyspnea, and dusky appearance of the face; rapid action of the heart, sometimes with feeble pulse; symptoms due to pressure by the fluid on the neighboring organs (trachea and œsophagus, etc.); great restlessness. These symptoms, it must be understood are due to the presence of fluid effusion. If the pericarditis remains dry, there may be no symptoms, or at most slight precordial pain.

It is evident that we must rely more upon physical signs than subjective symptoms for diagnostic information.

Physical Signs.—(1) *Before effusion of fluid.*—On auscultation is heard the characteristic "to-and-fro" friction rub, variable in intensity, and not accurately synchronous with the cardiac sounds. It usually begins at the base of the heart and then extends more or less over the whole surface. The friction may sometimes be felt by the hand (friction fremitus). It becomes less pronounced as the effusion increases, but is rarely entirely absent at the base until complete resolution or organization takes place.

(2) *Effusion stage.*—The physical signs are marked increase of the cardiac dullness; displacement of the apex beat; muffling of the heart sounds; displacement of other organs (if effusion is great). The shape of the dullness is characteristic. It is conical, the apex of the cone being truncated, and situated at the level of the second rib, owing to the close attachment of the pericardium to the great vessels at this point. The apex beat is generally pushed upward and to the left. It lies, when it is palpable at all, distinctly within the left border of cardiac dullness, not, as in enlargement due to valvular disease, in close relationship to it. The marked distention of the pericardial sac surrounds the heart limits of the organ itself. The amount of bulging and displacement of organs will, of course, vary with the amount of fluid present. As resolution takes place the friction returns, and may be very coarse in character. Muffling of the heart sounds is not always present, and is not entirely due to the presence of fluid. The muffling is therefore due mainly to weakness of the cardiac muscle from accompanying myocarditis, although where the quantity of fluid is very great, in serious and chronic pericarditis, this may in part account for it.—(Wheeler and Jack's *Handbook of Medicine.*)

Treatment.—"(1) Absolute rest in bed. (2) In the early stages, ice-bags or leeches to the precordia. (3) Treat the cause—if due to rheumatism be careful in the use of salicylates. They perhaps tend, if given early, to prevent cardiac lesions; but when these are established, their depressant action in large doses may be harmful. (4) Paracentesis should be performed if the effusion is very great, and does not tend to become less, or produces urgent cardiac symptoms. To promote absorption after the acute symptoms have subsided—(1) Blister. (2) Employ diuretics and saline laxatives. When these fail, paracentesis should be performed. The puncture should be made one inch from the left sternal margin in the fourth or fifth interspace. If the fluid be purulent, incise and drain. If an organism can be isolated from the fluid, vaccine treatment may be employed."—(Wheeler and Jack's *Handbook of Medicine.*)

3. *Decompensation*—"During the period of compensation the valvular disorder is disclosed only by its physical signs or by a lessened ability on the part of the heart to respond to unusual demands without discomfort to the subject (dyspnea, cyanosis, palpitation of the heart, etc.); this is the consequence of lessened reserve power. Gradually, as the myocardium becomes enfeebled, it becomes less able to withstand the vicissitudes of ordinary life and it dilates. The ensuing loss of compensation may develop suddenly and rapidly lead to death; usually it is of gradual onset and progressive; it may be temporary or permanent. For a time the heart is manifestly adequate to meet the demands of quiet life, but more or less distress (dyspnea, cough, cyanosis, palpitation of the heart, precordial pain, vertigo, faintness, slight and transient edema about the ankles, etc.) ensues upon exertion, excitement, a full meal, etc.; but the symptoms subside upon the restoration of quiet: the compensation is unstable. Sooner or later the heart becomes unable to maintain the equilibrium of the circulation even when the body is at rest; the aforementioned symptoms become more or less permanent: the compensation is lost. This condition may eventuate in death; but in many cases the symptoms gradually subside temporarily, and are followed by recurring relapses and partial or more or less complete recoveries. The first evidences of this failure of compensation are manifest in that part of the cardiovascular system immediately back of the chamber of the heart primarily involved: in valvular disease of the left side of the heart, therefore, in the lungs; but in most cases the lungs have been for some time engorged, so that speedily the congestive and other disturbances become manifest in the general venous system throughout the body. At the same time failure of compensation becomes apparent in front of the lesion in a lessened and irregular blood supply. The evidences of lack of compensation, then, are disclosed not so much by the physical signs referable to the heart, although these are important, as by the evidences of general

venous and capillary stasis and a small, weak, frequent, and irregular pulse."—(Kelly's *Practice of Medicine.*)

4. *Cerebrospinal meningitis* has an incubation period varying from a few hours to a weak or ten days. The onset may be gradual or sudden (generally the latter), and is usually marked by a chill and rise of temperature. Headache, rigid neck, and hyperesthesia are constant; and vomiting, and mental, motor and sensory symptoms are often present. In fatal cases paralysis, coma, and convulsions have been observed. The *diagnostic factors* are: The presence of the headache, retracted and rigid neck, and hyperesthesia; vomiting, fever, and convulsions; lumbar puncture shows increased pressure in the spinal fluid and the presence of the *Diplococcus intracellularis meningitidis.* The presence of Brudzinski's sign and Kernig's sign are also said to be diagnostic. *Treatment* includes the use of Flexner's serum (injected into the subarachnoid space after about 40 c.c. of the spinal fluid has been withdrawn). The patient is to be kept in a dark room, with his head elevated (but not flexed) and an ice bag applied to head and spine. Nutrient enemata may be required; both bowels and bladder need to be watched. Nervous symptoms may demand an opiate or chloral; urotropin is said to be of service.

5. *Scarlet fever.*—Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent.

Measles.—Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small dark red papules with crescentic borders, beginning on face and rapidly spreading over entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present.

Simple angina is characterized by absence of eruption, little or no fever, and the presence of pain in throat or tonsils.

6. *Otitis media* is a serious frequent complication of scarlet fever. The period of onset varies in different epidemics and in different patients. Generally it occurs soon after the disease is at its height. High fever and extreme pain in the ear are always present; the tympanum may rupture, and a discharge from the ear will be observed.

7. *Prophylaxis of tetanus* consists in the careful antiseptic treatment of every wound; and wherever possible, infected wounds should be excised and cleansed. Antitetanic serum may be injected in doses of 20 c.c. every 24 hours till symptoms cease. These precautions are particularly to be observed in punctured wounds, and wounds likely to be contaminated with soil, manure, etc., or by splinters from old wood.

8. Acute Dysentery. *Symptoms.*—Frequent diarrheal discharges containing blood and mucus, and accompanied by great tenesmus and abdominal pain; the temperature rises to 101° or 102° Fahr., the tongue is coated, anorexia is present, debility and emaciation appear. *Treatment* consists in rest in bed; liquid diet; an unirritating purgative such as castor oil should be given at the onset of the trouble; opium will relieve the tenesmus and check the peristalsis; hot stupes to the abdomen will relieve the pain; bismuth subnitrate has been used with benefit; intestinal irrigation is of use *after* the acute stage has passed. Ipecac, antibacterial serum, and salines have also been used.

9. Brain abscess. *Causes.*—Trauma; compound fractures of skull; penetrating wounds; spread of infection from ear, or from frontal, ethmoidal, or sphenoidal sinuses. "The *symptoms* in traumatic cases are acute and, as there is usually diffuse meningitis, there is intense pain, fever, and rigors, coma quickly supervening. In the more common chronic cases the symptoms are often vague in the early stages, but when well marked consist in signs of intracranial pressure. 1. The *headache* and tenderness are severe and localized to the site of the abscess. 2. The *temperature* is subnormal, unless there is associated meningitis. 3. The *pulse* is markedly slowed, even down to 30 or 40. 4. The patient is quite intelligent, but *cerebration* is very slow; vomiting and optic neuritis are usually present. 5. *Motor symptoms* may occur if the abscess is in the anterior part of the temporo-sphenoidal lobe, either irritative or paralytic. If the cerebellum is affected, there is giddiness both while walking and lying down, together with weakness of the hand grip and increase in the knee jerk on the side affected. Lateral nystagmus often occurs."—(From *Aids to Surgery.*)

10. *Asthma* is a paroxysmal expiratory dyspnea. It is supposed to be due to a diminution in the caliber of the smaller bronchial tubes; the cause is unsettled. It may occur as a symptom in cases of chronic nephritis (*renal asthma*), or in chronic heart disease (*cardiac asthma*); it may also be caused by the action of the pollen of certain grasses or plants on a particularly sensitive respiratory mucous membrane (*hay asthma*); certain irritants may also cause the condition (*bronchial asthma*). Heredity and various neuroses have also been considered as etiological factors.

Treatment during an attack.—"Remove any obvious cause of reflex irritation, such as overloading of the stomach. A brisk emetic often cuts an attack short; nitrites, especially nitrite of amyl, or chloroform may be inhaled. Belladonna, stramonium, and lobelia in combination with ammonia are useful remedies; the fumes of burnt niter papers, etc., are also recommended. A hypodermic injection of morphine may be needed; and pilocarpine or adrenalin may also be used hypodermically. The drug which has most claim to be regarded as specific is iodide of potassium. It should be given during the intervals and steadily persevered with. It is often successful, but as often fails, the disease being very refractory to treatment. *During convalescence.*—Change of air, careful diet, cod-liver oil, tonics, etc.—(Wheeler and Jack's *Handbook of Medicine.*) Pollantin has been recommended; and the condition of the nose should be attended to.

(*To be concluded.*)

Books Received.

CARCINOMA OF THE GALL-BLADDER.*

BY JOHN B. DEAVER, M.D.,

PHILADELPHIA.

ALTHOUGH we can contemplate with justifiable pride the great advances in medical and surgical treatment that have followed the introduction of ether anesthesia and the discovery of the source of infection and the means of combatting it, we are in no danger of losing the becoming grace of humility. For daily are we compelled to realize our limitations as we are confronted with that inexorable command "so far and no further shalt thou go." In no field of investigation does this injunction seem to be more insistent and persistent than in the search for the cause and the cure of cancer. Steady and untiring research, a voluminous and often tiresome literature have provided us with little more definite knowledge than that a constant persistent irritation of mucous or other skin surfaces often results in tissue changes and cellular proliferation with cancerous degeneration as the final outcome.

In the vast majority of ills which human flesh is heir to there is the beneficent gift of pain to herald approaching danger, but pain in cancer, as we all know, is too often the signal of despair. It is for this reason that recent investigations have been so largely directed to precancerous conditions, thus giving to preventive surgery the same importance that attains to preventive medicine.

Not only have we learned something about the early local changes that precede carcinoma but we have gradually been brought to a realization that in its earliest stages cancer itself is entirely local, and accordingly, whatever success has accompanied our efforts in surgical treatment is mainly due to early and radical surgery. The vital importance of this cannot be overestimated.

If cancer provides one of the dark chapters in medical literature, cancer of the gall-bladder may be said to have the unenviable distinction of providing some of the darkest pages in that chapter. Kehr, in one hundred personal observations of carcinoma of the gall-bladder, saw very few that were amenable to operation, and in forty-nine operations had only one recovery. A cancer of the gall-bladder that can be diagnosed before operation or one that can be recognized (without pathological examination) at the operating table is also one that bears the ominous label "too late."

Statistics differ widely as to the relation of gallstones in the incidence of carcinoma. In my experience calculi were found in 89 per cent. of carcinoma, while in six consecutive pathologically proven cases within the past five years gallstones were present in all. But whether the incidence be as high as these figures indicate or whether it be as low as Chandler's experience of only two instances of carcinoma in 315 cases of cholelithiasis, we cannot ignore the possibility, especially as we know that the calculi are not the result of tumor formation since secondary cancers of the gall-bladder do not produce gallstones.

Thus gallstones are an important item in the etiology of carcinoma of the gall-bladder. In line with modern preventive measures it becomes a vital necessity to prevent if possible the formation of gallstones, or failing this, to avoid the possible consequences which the irritation of their presence may cause and remove not only the gallstones but the primary source of infection that has given rise to their formation.

A careful observation of the reported cases of carcinoma of the gall-bladder reveals the fact that in the vast majority of instances there has been a history of an apparently harmless type of "gall-bladder dyspepsia." Smithies, in his twenty-three cases has observed this in sixteen, the true nature of the disorder showing itself after an average of nine years, with a minimum of three years and a maximum of 36 years duration; while the period of aggressive symptoms ranged from five weeks to three years. In my experience of 16 cases of carcinoma of the gall-bladder (6 pathologically proven, the others inoperable or diagnosed at laparotomy), among 1,000 operations for gallstone disease, much the same fact appears as to the duration of upper abdominal symptoms, the longest period being twenty years and the shortest two years.

Of course not all of these cases were serious in the early stage, but I venture to say that there certainly was a time at which the character of the trouble was such as to demand serious consideration, if for no other reason, by the very fact of recurrence after suitable medication, which so evidently had failed to attack the primary source of infection. Rosenow's researches with regard to the route of infection from such sources and the special affinity of certain organisms from these primary foci for the gall-bladder and stomach are familiar to all of us. I have no rea-

*Read before the College of Physicians, Philadelphia, June 4, 1919.

son to depart from my belief that the most fruitful primary source in all upper abdominal infections is the appendix. The presence of bacteria of more or less virulence in cases of cholecystitis in conjunction with abrasions of the mucous surfaces of the organ involved certainly represents a favorable opportunity for the lodgment of the infective process. Infection of the gall-bladder may also take place in other ways; through the portal circulation from an inflammatory process in the digestive tract, the bacteria being then excreted with the bile and passing into the gall-bladder; or it may ascend through the bile ducts; or it may be carried by the blood; or finally it may be brought about by contiguity from neighboring organs. The purely infectious character of cholecystic disease has been emphasized during the war, during which there seemed to be a notable increase in this disorder, especially in Germany. Albu has traced the increase to the greater prevalence of typhoid and diarrheal diseases and also to the war diet with its unusual combinations of food taken at a meal, which give rise to catarrhal conditions and retrograde infection of the biliary tract. The frequency with which young people are attacked and the absence of any familial disposition to the disease are additional evidence of its purely infectious character; it seems furthermore to be supported by the increased incidence during the war of infective catarrhal jaundice, also due to faulty alimentation.

The sequence of infection and possible carcinomatous degeneration is also apparent in pathological studies in the surgery of the gall-bladder. The early changes in cholecystitis consist mainly of enlargement of the villi from congestion and leucocytic infiltration, a condition which may or may not be the precursor of calculous formation. The enlargement later on develops into erosion of the epithelium of the villi or one or more of the villi may develop into papilloma, the tendency of which to malignant degeneration is well known. It is true that only rarely does the surgeon have the opportunity of seeing the process in its earliest stage. A few instances have been described, the most recent that has come to my notice being a case reported by Hrushka. In this, there was evidence of chronic inflammation with polymorphous hyperplasia of the epithelium showing a marked tendency to deep growth and invasion by proliferation of the latter, and also by its invasion into the gall-bladder mucosa. The various stages from villous enlargement to malignancy have been well portrayed by McCarty of the Mayo Clinic.

Like malignant disease of other abdominal viscera early carcinoma of the gall-bladder can rarely be diagnosed clinically. The symptoms vary from a mild gastric catarrh to a severe cholecystic inflammation. A neoplasm situated within the gall-bladder may remain symptomless and may even perforate the wall and attack the serosa without necessarily arousing suspicion of its grave nature. In the neck of the gall-bladder, of course, a neoplasm is not so apt to remain quiescent; but even here, if no calculi are present in the cystic duct and the contents of the gall-bladder are sterile, the serious condition may remain unsuspected. The combination, however, is rare. Stones are usually present and are infected, and occlusion of the cystic duct from the proliferating tumor leads to severe cholecystitis, but a clinical diagnosis of malignancy is not possible. The patient is rarely cachectic, there is no evidence of ascites and generally no palpable mass; at the same time laparotomy often reveals inoperable carcinoma of the neck of the gall-bladder. But a review of the history of these cases often reveals the story of one or more severe attacks of gallstone colic, timely treatment of which might have obviated the unhappy end-result.

The question arises, is it wise to operate in every case in which a diagnosis of gallstones is made, as for example when the disturbance affects a young person not of the so-called cancer age. I would say yes, if the attack recurs. Suppose laparotomy reveals only a mild cholecystitis or small calculus or calculi; it certainly was justifiable even though the case in question may be one of the many that do not develop carcinoma. For while they are on the whole, fortunately, few, we have absolutely no way of foretelling which will and which will not undergo malignant degeneration. There is no use in waiting for jaundice or for physical evidence of tumor by percussion or palpation. Percussion in cholelithiasis gives little information; and while a palpable mass may be due to hydrops or to empyema, in both these conditions the neck of the gall-bladder usually is displaced and there is no way of telling whether it contains a stone, stones, or a malignant tumor. Carcinoma may generally be taken for granted if a palpable mass in the gall-bladder region is irregular, that is, rough and uneven to the touch; but it must be remembered that thickened omentum often gives the impression of an irregular mass. I believe I am in no way reflecting on the diagnostic value of the x-ray in saying that it does not differentiate carcinoma of the gall bladder from a benign condition of the viscus.

The difficulty of diagnosis is sometimes as great in late as in early cancer. In view of this it is as unwise to abstain from inspection in suspected malignant disease of the gall-bladder as it is in the early cases. Not a few cases that clinically suggested cancer have proven benign. In spite of the high mortality of operation for cancer of the gall-bladder I would give every patent the benefit of the doubt, except in the presence of such unmistakable evidence as enlargement of the liver, a hard irregular mass, jaundice, ascites, cirrhosis, cachexia. And I would be happy if but one case in a hundred prove benign to have saved that one; just as happy, in fact, if by operative interference in one hundred cases of cholecystitis only one or two had been redeemed from the danger of malignancy.

My experience has led me to conclude: That every case of cholecystic inflammation that does not yield to medical treatment within a reasonable time should be given the benefit of operation.

Operation in all cases of gall bladder infection, whether calculous or noncalculous, should include the removal of the appendix as the prob-

able source of infection and the examination of other upper abdominal viscera for associated disease.

A preoperative diagnosis of carcinoma of the gall bladder in its early stage is not possible; and in the late stage a mistaken clinical diagnosis may sometimes be made. The early cases should have the benefit of operation in order to remove the menace while it is still local and eradicable; the latter are equally deserving of laparotomy, at least, in the hope of finding a benign instead of a supposedly malignant growth.

Carcinoma of the gall-bladder cannot wait upon diagnosis. It must be treated before it can be diagnosed.

"THROUGH THE JAWS OF DEATH, BACK FROM THE MOUTH OF HELL."

By W. B. KONKLE, M.D.

MONTOURSVILLE, PA.

"Her lips were red, her looks were free,
Her locks were yellow as gold;
Her skin was as white as leprosy,
The Night-mare Life-in-Death was she,
Who thicks man's blood with cold."

The Rime of the Ancient Mariner.

ANY revelation of personality that may be indicated in the discussion to follow will be, from the nature of the inquiry, of the character of self-revelation. But such self-confession will so little bear the brand of individualism, will, on the contrary, be so impressed with the generic quality, that there will be brought to mind no suggestion of Aurelius Augustinus, nor Jean Jacques Rousseau, nor Thomas De Quincey. Distinctions of age, sex, and temperament will still farther remove from comparison Maria Constantinovna Bashkirtseff. An isolated, specific example will, indeed, be taken as the model of a picture to be sketched, and as the source of data upon which to base judgments. Yet the particular case chosen is so typical, so accurately representative of a numerous group, that the induction employed may, nevertheless, stand the test of criticism.

Neurasthenia is the subject of our story—neurasthenia due to intestinal toxemia. Each of the autotoxemias may have its symptom complex in the nervous system with features of its own. So neurasthenia may manifest variations to correspond to the varied self-poisons that enter the blood stream. The nervous disturbance caused by poisons originating in the intestinal tract has shades and markings peculiar to itself. Thus the term neurasthenia is not the symbol of a single and constant concept; and, hence, may lead in some degree to confusion of ideas. But, as in more common use indexing a syndrome associated with the condition of intestinal autointoxication, the name is not objectionable. Besides, it is stamped upon the thought of the doctor and burned into the consciousness of the sufferer.

Who shall paint this bloodless, soulless demon that dries up the springs of life until, low and stagnant, they yield only living death?—that brings you to the locked door of the tomb and then mockingly withholds the key? Who shall tell what of torture it means to be in a world without being a part thereof—to stand among men, and not be of them? The terror of a dream existence from which you cannot waken, yet which never leads to Lethe's wave, the horror of moving as a ghost amid realities or as a reality amid ghosts, the agony that merges all other prayers in a frenzied prayer for sleep, these things and more are wrapped up in the smooth-sounding word from the Greek tongue, *neurasthenia.*

The utter wretchedness of the neurasthenic state may be measured by the joy of deliverance from it. None but one who has escaped from the clutch of the "Night-mare Life-in-Death," and has been, as it were, reborn to the world, to sunshine, to heartfellowship, to action, to thought, to hope, none but one thus redeemed can know the span of the transition from perdition to paradise.

To say that disease should be controlled by laying an inhibiting finger upon its cause is to express merest platitude. Proneness to error at this point is, notwithstanding, quite evident. Thus considered, our term neurasthenia is unfortunate because misleading. Possibly in rare instances it may include the idiopathic; but most commonly its range does not extend beyond the symptomatic. To differentiate and signalize more clearly the disease entity we wish to keep in view, let us at this point drop the word neurasthenia for the strictly logical and scientific designation intestinal autotoxemia.

In the cases in question we have, then, an autotoxemia, the determinative toxins of which are generated in the bowel as products of fermentation and putrefaction. The occasion of such decomposition is choke or block of the canal due to obstruction or torpor thereof, and resulting in prolonged retention of the bowel contents. Intestinal stasis is a phraseology in vogue indicative of the condition. As an outcome harmful gases and liquids pass into the blood stream doing damage of sundry sorts, but working most conspicuous and appalling havoc within the nervous system. In a certain proportion of instances the condition is unmistakably manifest, and the treatment, consequently, plainly foreshown. But in the remaining large ratio of cases the actual state is concealed or masked. The bowels may be regular in action, yet chronically loaded. Regularity of movement does not in itself insure completeness of movement—normal periodicity is not equivalent to normal sufficiency. Little, partial, fractional passages—slimy, frothy, fetid feces—periods of half-constipation alternating with spells of abrupt, forcible, profuse diarrhea—all this is indicative of retention, accumulation, with decomposition, of the intestinal contents. Like a railway locomotive, the corporal engine should regularly dump its ashes. Now not just any kind of a passage constitutes a "dump." If one would be well his bowels with proper periodicity must *unload*—he must with religious punctuality *dump his ashes.*

Intestinal stasis may be wholly due to torpor of the bowel. Such cases are amenable to treatment by medicinal and mechanical methods—can be doctored to a cure. In most instances, however,

we have to deal essentially with more or less pronounced organic obstruction—it may be of the nature of congenital abnormality, or adhesion, or stricture resulting from inflammatory processes or from abdominal operation, or incomplete hernia, or may, perchance, involve some rarer factor. In this numerous class if absolute cure be in any event attained it must be by surgical procedure—as a matter of course organic obstruction cannot be doctored away. And surgery may fail, too; it may not be able to compass the requirements for relief, and it may leave more adhesions and strictures than it finds.

Hence, of the cases in question many will remain admitting of palliative management only. These will at last come back into the family physician's hands for him to do with them the best he can. Now the best he can do is to dominate boldly the situation, to bring unhesitatingly to bear agents to offset the pathological tendencies, in the irremovable abnormalities to enforce and maintain artificial compensation. And the causes of disturbance of function being unalterable and constant, counter-measures must be practically continuous—may be relaxed merely to the degree of brief remittancy or intermittency. This is our point of greatest emphasis. It may be a storm center; but here we take our stand. Where there is predisposition to intestinal stasis by reason of organic obstruction, keep those bowels unloaded, and continue to keep them unloaded, and continue, and continue, or there will supervene autotoxemia with the hell-pack of neurasthenia at its heels. *Dump those ashes*—in that sign conquer.

How shall such recurrent and thorough expulsion of fecal residuum be accomplished? Expedients and devices galore are expounded and exploited. But, ordinarily, in the long run, resort will be had to medicinal laxatives. Nature seems to be forehanded in the matter—to have provided for the necessity by furnishing an unusually long list of these substances. In this multiplicity and diversity lies the opportunity of easier and more successful solution of the problem. Judicious and tactful selection, combination and interchange will largely obviate habit and tolerance. First this and then that, now this class and again that class, thus the objective is surely and invariably reached. If there be a supreme lord of the list, in the writer's judgment it is aloes—one will not go wrong in tying to that the main cable of his faith. Said an able physician of our acquaintance, "If I take an aloes pill at night I feel well; I cease to feel well if I omit it." The enunciated doctrine is heterodox, truly. Orthodoxy sanctions rather that you cram fruit and vegetables, stuff with bran, roll over a barrel or roll a barrel over you, do anything and everything except take a laxative dose that might be called medicineé Yet when the bowels must be moved what boots it whether it be done with figs or with senna? Does not may-apple hold rank in the vegetable kingdom as refined and noble as the onion? Nature's temple has no court of the Gentiles.

Taking leave of our theme, a word may be permitted as to the merit and worth of the physician's service rendered in relief of intestinal autointoxication. A man stewing in his own juice is a classical metaphoric conception that will find literal interpretation as applied to this condition of utter misery. Bunyan's pilgrim was overjoyed when his burden fell from his back. Similar deliverance the mind feels that is unburdened of the crushing weight of neurasthenic wretchedness, suffering to which pain would be a solace. Analogy still more terrible is suggested by an old Roman means of execution. To the victim was bound a rotting corpse which he must bear about with him until emancipation came with death from loathing and exhaustion. That, good doctor, is your neurasthenic patient. As an angel of God loose his bands and set him free. *Dump those ashes!*

INTELLIGENCE.

By B. LEMCHEN, M.D.,

CHICAGO, ILL.

PHYSICIAN TO THE CHICAGO STATE HOSPITAL.

INTELLIGENCE is not confined entirely to nerve cells, but all cells possess it; even such low forms as bacteria have been able to survive in spite of antibodies and treatment that has been advised for their destruction. This is shown in the epidemic history of a disease—first the people in different parts of the community are attacked with indefinite symptoms, and by the time the disease is recognized a great number of people are attacked, then it recedes from this community to attack another. In the recent epidemic the organism or organisms have attacked almost the entire globe, and in spite of this the offending organisms have not even been isolated. The leucocytes will in an infection push themselves through surrounding blood vessels, will digest bacteria and secrete ferments that are destructive to the same; they will also infiltrate the lymph channels to prevent the spread of an infection, but they have no connection with neurons.

The uterus will contract and expel its fetus at a given time, according to the species, even when its connection with the nervous system has been severed. By injecting secretion into the circulation, the liver and pancreas will be made to secrete regardless of nerve stimulation. All this requires some degree of intelligence. What is intelligence, if not the power to survive? However, the needs differ so much in the different species that the reactions must also differ. In the unicellular organism, each cell can exercise its own intelligence, while in the multicellular organism, it was soon found that for the existence of the organism, each cell cannot exercise its own intelligence, but the intelligence from the cells must be gathered and modified by special cells which we call neurons, and in man we call this "Mind."

Mind is a biological force produced by all the cells of the body, of which the nerve cells have specialized themselves in gathering, modifying, storing, transmitting, and liberating it for the need of the organism. However, the nature of the force is not known except that it follows definite physical, chemical, and biological laws which, in the stages of development, have been found the best for the organism. Whenever the force does not follow those laws, a change in the individual's behavior results.

Since intelligence depends on the cells, a study of them is necessary. But neither the chemical composition of the living nor the molecular arrangement of the healthy, the diseased, or dead cells is known.

At least three biological properties are possessed by even the simplest cells: (1) Metabolism. Every living cell is capable of taking suitable material from its surroundings and converting it into its own substance, rejecting anything that is of no more use to it. (2) Reproduction. Every living cell is capable of reproducing other cells of its kind. (3) Irritability. Every living cell responds to external stimuli. Bacteria, for instance, will grow only at a certain temperature; they will produce resistant spores in case conditions for their existence are not favorable. An amebas will lie dormant on a slide until heat is applied to the slide, when it will move, etc. A fourth property may be added, and that is producing, retaining, and liberating force. Metabolism, reproduction, movements, and spore-formation require force which in the unicellular organism must be produced, retained, and liberated when needed, as the force is not used all the time.

All this surely requires some intelligence. In multicellular organisms the four laws above enumerated had to be modified to meet special conditions. Take, for instance, man with his needs and the different environments. His cells could not go on and multiply indefinitely, consume each other, or respond to every external stimulus and still exist. For that reason, cells have organized themselves into tissues and organs for special functions—bone for frame, skin for protection, the alimentary tract for digestion, sex glands for reproduction, etc.

For obvious reasons also the force produced by the cells is used by them after only it has been modified by special cells, which we call nerve cells or neurons; and the sum total in man is Mind. Cells propagate a force which I designate as biological force. In the unicellular organism force is stored and used by each cell itself for metabolism, reproduction and irritability. In the multicellular organism the force is first collected by the neurons, then modified, stored, and transmitted to all parts for the benefit of the entire organism. The places where this force is modified we call the special centers, and where it is stored we call the associated centers. The higher in the scale is the animal, the more the special centers and associated centers are developed. By comparative anatomy we actually can trace the development. In the lower forms the nervous system is composed of a straight tube surrounded by neurons with enlargement at the cephalic end, known as the cerebral vesicles. The force collected by the sensory neurons is transmitted to the motor neurons without any modification, and it is more or less what we call reflex action. But in the higher degrees we find that, while the organism is still maintaining a tube from the cauda up to the midbrain with neurons surrounding it and engaged in transmitting the force collected by the sensory neurons to the motor neurons in a somewhat modified reflex movement that does not require judgment, yet the primary vesicles have enlarged with millions of cells surrounding and have formed a forebrain whose function appears to be to connect and harmonize all parts of the brain. The cerebral hemispheres are where the special centers are located that modify the force brought to them by the sensory neurons and transmit it to the associated centers where it is either transmitted to the motor neurons for action or retained for further use or used with previously acquired force for images, thinking, projecting, etc.

Nature has tried to supply every species with as much force and force of the proper kind as is necessary for the perpetuation of that species. However, nature does not always succeed, as a good many species have already ceased to exist. In the lower forms of life where the needs are small, development is not advanced, and life is of short duration; there are only sufficient neurons to gather the force from the bodily cells and transmit it to motor neurons. In the higher organisms, where the struggle for existence is harder, development more advanced, and life longer, neurons must be reserved for storing force to be used also in instinct movements. In still higher degrees, where more intelligence is necessary, neurons must be reserved for modification of the force before it is transmitted to motor neurons for action, so that the animal may judge whether it should act or not. Take for instance, man. It takes him almost 18 years to develop before he can be self-supporting. His life lasts about 70 years. His needs are greater than those of other animals, and he is by no means the strongest of the animals. Naturally his struggle for existence is great and for this reason it is necessary for him to possess keen judgment. However, some organs must work at all times and no compromise is possible. The heart must beat, even when a large vessel is cut, because when the heart stops beating it means death. The same is true of respiration, digestion, elimination, etc. For this reason some neurons constituting what is known as the sympathetic system, at an early age of evolution separated themselves to act independently of the central nervous system, though still maintaining a connection in an indirect way. These act in changing the pressure in all or separate parts of the body, contracting a vessel when it is open (so arresting hemorrhage at times), and dilating it where it is closed. The same automatic action occurs in respiration, digestion, elimination, etc.

Forces that are not absolutely necessary to life are first collected at special centers, modified, and transmitted to the associated centers, so the latter can judge whether or not they shall send force to the motor neurons for action. For instance, when a man walks in the woods and he sees food, he may be hungry and want to take it, but he hears the roars of savage beast near where the food is, and he knows it is too dangerous to go and take the food. But the physical forces of the different senses differ. Of sight they are undulating, ethereal waves, of hearing air waves, of smell gaseous contract with olfactory nerves, etc.

The physical forces are first received by special organs where they are transformed into biological forces and transmitted to the special centers, where they are again modified, part retained and another part transmitted to the associated centers; here they are compared with previous forces of the same or other centers and a judgment is formed as to how they shall be disposed of, whether the force or forces

shall be retained or transmitted to certain motor neurons for action in a certain part of the body, or projected to the periphery. Consciousness depends on the acuteness of the special and associated centers, and the more perfect the neurons in the special and associated centers are, the clearer is the consciousness and the better is the judgment.

The neurons in the hemispheres need rest and at times they do suspend action, and that is what we call sleep. Then there are times when the neurons in the special centers suspend action, while the neurons in the associated centers are in action, the person being in a state which we call half asleep. Now what will happen? Force from the periphery, whether it is due to a heavy meal in the stomach or noises reaching the ears, will reach the special centers, but they are asleep or not functioning. Some force, however, will be transmitted to the associated centers unmodified. The associated centers not being accustomed to that kind of force will try to compare it with previous forces in different parts of the associated centers and in this way a person may, during sleep, see, hear, smell, or experience many other things, as in what we commonly call dreams. The forces may even be transmitted to motor neurons and the person may perform almost any kind of action, of which when awake he may not remember anything, as unmodified forces are not stored in the associated centers. The same forces may also produce convulsions. It is a fact that in the majority of cases idiopathic epilepsy begins at night, the attack being due to some peripheral stimulation. Of course the convulsions when not checked may so weaken the special centers that the latter may go to sleep in the daytime, so that the subject will have epileptic attacks during the day. Some forces may be irritating to a special center, sensitized by a previous experience, which will transmit them to the associated centers unmodified, and the person may have dreams, do odd things, or even have convulsions; at the same time the special centers may receive other forces, which they modify and transmit to the associated centers. In other words the person may be awake when he does all these odd things and still cannot help doing them, and this we commonly call hysteria. The cells in the special centers may be poisoned, either by a drug intoxicant or infection, and allow peripheral forces to reach the associated centers unmodified, and so the patient may experience all kinds of hallucinosis and clouding. The degree of clouding will depend on the number of intoxicated cells. All the cells in a center or centers may be poisoned and the person will be in a delirious or unconscious state. In others some cells in a center may be poisoned, while others are not and are able to modify peripheral forces; such a person may not be able to recognize an object at one time, but may recognize it at other times, or may not be able to answer questions at one time but may answer them at other times, depending on whether the force reaches toxicated or non-intoxicated cells in the special centers before it is transmitted to the associated centers. In others again, the neurons transmitting the force from the special to the associated centers will be toxicated and will allow the force to travel back to the special centers and to them all. Such persons may see, hear, smell, etc., and they will react to what they see and hear. While in dreams, hysteria, and some of the intoxications, the persons have insight and know they are imagining, in those intoxications where the neurons transmitting the force are also poisoned, everything seems real and the persons never have insight during the time of their hallucinosis or even for some time afterwards.

There are conditions in which the cells in the associated centers become weakened, and while the forces may be transmitted to them modified, they will not elaborate them normally by comparing them with forces stored during their existence but will compare them with inherited forces that the neurons themselves propagate, and so will develop morbid ideas or delusions. There are conditions where neurons in the special associated centers and neurons that are transmitting the forces become weakened and in such the patient will develop delusions and hallucinations, and in fact will not be able to adjust himself to the ordinary conditions of life. Such a state is due to an inherited weakness of the neurons, and is known as dementia precox. There are also other conditions to be considered where the body cells outside the neurons are not functioning properly. Either they liberate a greater amount of force which will spread out on a greater area at the associated centers, producing the so-called flight of ideas, or they liberate a less amount and then some time will be required before enough force will accumulate at the associated centers to cause them to respond and transmit it to the motor neurons, and we then have slowness of thought and motion. It seems when a greater amount of force reaches the cortex it produces euphoria, and when a lesser amount reaches the cortex it produces a depression. Also wherever a greater amount of force is used by efferent neurons than is brought to the cortex by the efferent nerves, fear and anxiety are produced. This is true in the mixed phase of manic depressive insanity, where the body cells liberate a less amount of force and the person is restless and using up force; and also in neuroses where, owing to an exhaustion of the neurons, all the force liberated by the body cells is not transmitted to the cortex.

Treatment.—In neuroses where there is an exhaustion of the neurons, rest with a selective diet is the most important. In hysteria and epilepsy, when seen early, we must try to find out what center is at fault and what forces are irritant to that center, so that it allows them to reach the associated center unmodified, and this can be accomplished by persistent questioning of the patient, which may be called psychoanalysis if you please. Of drugs, the bromides that also lower the activities of the neurons in the associated centers, and chloral that lowers the activities of the peripheral neurons, may, when used with caution, do good. However, considering the degenerative changes produced by bromides on the brain and chloral on the heart, their general use cannot be recommended.

In the manic depressive group we must try to put the body cells in good condition by proper feeding and elimination, and in the manic phase give our patients some work to rid themselves of the surplus force reaching the associated centers, and by all means not to use anything that may weaken the neurons and convert a manic into a dementia precox. If possible, do not use hot packs nor hot baths

that have a tendency to exhaust the neurons, nor opiates, but use small doses of nux vomica, which is a good nerve tonic. In case the patient does not sleep well, a little paraldehyde in a little milk will produce sleep and will not harm.

In the dementia precox group, everything has been tried and nothing has proved of much value. It is hardly necessary for me to mention that general hygienic measures must be used in all mental conditions and that symptoms must be treated as they arise, and that the best remedy is prevention.

THE EVOLUTION OF PODIATRY.

By H SCHEIMBERG,

BROOKLYN, NEW YORK.

IN perusing the recent history of medical achievement, one is perplexed at the great progress made. So confusing is the increase of knowledge in all branches of medical science that it is practically impossible to select one field whose advances have been most pronounced. Yet a brief survey of the growths of medical specialties, discloses a phenomenon of great utility to the race: I refer to the evolution of a distinct branch of medicine now known as Podiatry (or Chiropody) from that despised and obscure trade of the "corn-cutter." So quickly has the transition occurred and so vast in its scope is the growth of podiatry that it is difficult to know where to start the narrative. This difficulty is intensified as we approach the history of this development from the standpoint of either its literature, its proponents, its legislation, or its research work.

Before, however, relating its history, it is perhaps desirable to refer to such thoughts as naturally arise in our minds when we think of feet. To medical practitioners, the query suggests itself of why feet have been neglected as a study. We think of the numerous articles appearing in recent years both in medical and lay literature on the subject of foot lesions; of the increasing widespread agitation regarding flat feet, for example; of the problems that confronted the medical authorities of the army in connection with feet and shoes. It occurs to us also that we have been seeing an increasing number of advertisements in the press extolling the virtues of various types of shoes and arch supports. We wonder at the fact that early in the history of recruiting in connection with the world war, the authorities conceded that a large percentage of the rejections were on account of bad feet.

In amplifying these thoughts, we ask why there has been the undeniable disregard by medicine in the past of foot lesions—why it has divorced the foot from its observation and thus retarded the acquisition of knowledge of a part of the body with which the efficiency of humanity is intimately concerned. It is apparent that in minimizing the importance of foot pathology, medicine has overlooked the value of a part that the greatest military tacticians from time immemorial have recognized as of essential importance in military life. The fault may have been with the schools which never taught minor foot ills. We know that post-graduate medical schools have never taught practitioners along lines of foot care. Of no less importance are the feet in civil life. It is already becoming axiomatic to medical practitioners that "rheumatism," "nervousness," "growing pains," and various other appellations are often synonyms for a variety of mechanical disorders originating in the feet. The practice has been to regard most foot or leg pains as "rheumatic" and to medicate internally by salicylates or other drugs. Others, again, overlooking other causes, attributed most foot ills to "flat feet" and the pendulum is swinging over to a promiscuous application of arch supports and well advertised shoes as cure-alls. By depending upon arches or brand shoes, which are in most cases applied by unscientifically trained shoe clerks, practitioners have ignored a comprehensive etiology for conditions often originating from other sources than feet and which were reflecting themselves locally; and in this dependence on well-advertised shoes fitted by shoe clerks, sometimes called "doctors," the important fact has been lost sight of that the therapeutics of a shoe does not lie in its name but in a properly adjusted shoe for the particular condition, under the guidance of an orthopedist or podiatrist. Others, again, have entertained a notion that general disturbances manifested by pain below the abdomen will right themselves and therefore warrant no special attention. Recent research, however, enhanced by the studies of orthopedists and of podiatrists are rapidly changing this unfortunate state of affairs. Lack of knowledge in foot pathology has resulted in the existence of fallacious notions as to feet. A glaring example of this obtains in the very common but false notion that a low-arch means a useless or flat foot and that a highly-arched foot is ideal. Such a view, by way of illustration, herein, is in the light of newer knowledge rapidly becoming obsolete.

As indicating the growth of medical interest in foot lesions, we would refer to the many articles current. The number of such writings has probably increased ten-fold in the last seven years and is naturally concomitant with the alarming increase of foot ailments in our large industrial centers. This interest is, prima facie, indicated in the more concentrated study given it by eminent orthopedists in connection with the brilliant orthopedic advances of the last two decades. In military life, this interest has been very intense. The feet became a problem not only in the light of the numerous rejections from service occasioned, but also from the loss of man power which occurred as the result of many soldiers being incapacitated from service on account of poor feet. The United States Government through an official board, the Munson Shoe Board, devoted four years to a close study of feet and shoes, which resulted in very valuable information and in the production of the Munson-last shoe.

With further reference to the growing sales of "orthopedic" or well-advertised shoes and arch supports, we again see evidences of importance in this connection. Incidentally we observe a frantic, foot-sore, and somewhat crippled nation turning to an unscientific quarter, the shoe-store, for relief that should be had from practitioners

specially qualified. These are facts amply confirmed by clinical histories of patients who eventually arrive at some dispensary—for treatment after years of experimentation with various makes of shoes and supports recommended by laymen.

A survey then of the facts mentioned leads to one conclusion, namely, that as all sciences, and particularly medicine, are divided into specialties, the demand for those trained in foot ailments has been imperative. However, as medicine disregarded the responsibility, it eventually fell to the podiatrist to assume the task. That the podiatrist met and rose beyond the responsibility is a matter of historical fact. And this brings us then to the story of the evolution of podiatry as a profession.

The term "chiropody" in its earlier sense embraced that form of surgery dealing with the treatment of ordinary excrescences by the knife. The newer term podiatry, an evolutionary outgrowth of the older one and which is superceding "chiropody," means "the treatment of the feet in health and in disease."

As no one ever undertook to specialize in the treatment of such disorders, this work originally took on a trade atmosphere and its primitive history follows the route of early medicine or dentistry, that is, treatment given empirically in cosmetic establishments. As in early medicine and dentistry, chiropody was done by those unscientifically fitted for the work and thus limited in ability. The layman, however, was unconscious of the limits of chiropody. He was very conscious of the fact that his doctor minimized the pain in the lower extremities and even refused to examine or treat him. The layman, therefore, turned to the chiropodist for assistance.

As a trade, the practice of the chiropodist was often transmitted from generation to generation. Many of these individuals existed and plied their trade in barber shops and in boot-black stands, and others operated by moving from town to town much as the traveling doctor of old or the itinerant dentist. The itinerant chiropodist disappeared with the advent of the scientific podiatrist and the regulation by law of the treatment of foot ailments as a branch of medicine.

Concerning the history of podiatry in a State where its growth was peculiarly interesting, we shall consider New York State. The conceptions of chiropodists and their limitations, already narrated, continued in this State until these individuals themselves, self-educated, realized that their occupation demanded more serious attention. They sensed the vast importance of their work and their lack of training for the variety of pathological conditions that they met in their practice. Inspired by the necessity of action, in 1895, several pioneers conceived the idea of applying to the State Legislature for a law regulating chiropody, and in the same year this law was placed on the statute books as Chapter 864 of the Laws of 1895. This law also created the Pedic Society as the licensing organization.

Since the establishment of this first law, the history of the profession has been one of vigorous advance accompanied by an increasing respect and admiration for the services and scientific knowledge of its members.

By a section of the former law of 1898, chiropody was legally defined for this State as follows:

> Chiropody is understood to be the surgical treatment of abnormal nails, all superficial excrescences occurring on the hands and feet such as corns, warts, or callosities, and the treatment of bunions; but it shall not confer the right to operate upon the hands or feet for congenital or acquired deformities, or for conditions requiring the use of anesthetics other than local, or incisions involving structures below the level of the true skin.

The foregoing was a very unsatisfactory definition in that it made almost every act of the chiropodist illegal. The conditions that chiropodists were called on to treat were far ahead of the law and it was almost impossible to practise without overstepping the technical limitations of chiropody as there defined.

In curious contrast and as recording one of the most brilliant advances of podiatry in this State, we shall now turn our attention to the new definition of podiatry, passed unanimously by both Houses of this State and approved by the Governor very recently. It reads as follows:

> Podiatry shall be held to be the diagnosis of foot ailments and the practice of minor surgery upon the foot limited to those structures of the foot superficial to the inner layer of the fascia of the foot; the palliative and mechanical treatment of deformities and functional disturbances of the feet; but it shall not confer the right to treat communicable or constitutional diseases of the bones, ligaments, muscles, or tendons of the foot, or any other part of the body, or to perform any operation on the bones, ligaments, muscles, or tendons of the foot involving the use of any cutting instrument or the right to use any anesthetics other than local.

The laws of this State were consolidated by legislative enactment in 1909, and the law governing the practice of chiropody was incorporated as Chap. 13 of the Public Health Law. This Public Health Law which governs the practice of medicine, dentistry, etc., therefore, classed podiatry with those other great agencies for the improvement of the public health.

By Chap. 199, Laws of 1912, the licensing power for podiatrists was vested in the Board of Regents who demand the customary requirements as in other professions relating to fee, age, character, preliminary education and including graduation from an institution maintaining a standard satisfactory to the regents. The Board of Medical Examiners were from then on required to prepare the examinations for applicants for licenses which are issued only after passing the examination by this Board and previously fulfilling the preliminary academic requirements. These academic requirements for podiatry will in September, 1919, be 3 years of high school work, or the equivalent; and in September, 1921, 4 years of high school work or the equivalent.

The institution in this State which is training the podiatrist, is under the jurisdiction of the State Education authorities and was established in 1913. On Sept. 27, 1917, the regents granted a provisional charter which changed its name to "The First Institute of Podiatry," and abolishing the older title of "The School of Chiropody of New York."

Dr. M. J. Lewi, its president, prior to his assuming charge of the school had acted as sec-

retary of the N. Y. State Board of Medical Examiners for twenty-two years. His connection with podiatry started in a curious manner. A committee of the Pedic Society of the State of New York were referred to Dr. Lewi for advice as to methods of advancing the professional standing of the podiatrist by improving the then chiropody law. Dr. Lewi immediately fell in with the earnestness and the progressive intent of this committee and granted them extremely valuable aid by drafting the bill which was enacted in the spring of 1912 and became effective that year. The State Education Department then delegated Dr. Lewi in his official capacity with the medical board to outline a standard for chiropody schools. This standard was so high that it was necessary to secure as the leader of such an institution not only a medical practitioner but a medical educator of executive ability. In desperation, this committee finally appealed to Dr. Lewi to carry out the standard he had himself set by becoming the president of the school. Though at first averse to this offer, he finally left his position with the State Board and became president of the First Institute of Podiatry on January 1, 1913.

A survey of the curriculum of this institution is complimentary not only to the educational attainments of the podiatrist but also to the high standards set by the educational authorities of this State as to professions. The subjects taught at present embrace anatomy, physiology, histology, mechanical physiology, chemistry, bacteriology, microscopy, surgery, pathology, materia medica and therapeutics, orthopedics, practical podiatry, pharmacy, footgear, dermatology, principles of medicine, massage, and ethics. The scientific consideration of the foot, as being carried on in the First Institute of Podiatry, should be welcomed by the orthopedic surgeons, for its foot work, by reason of the agitation inaugurated to interest the public, is multiplying the number of their patients for foot ailments, many of whom find their way to these specialists through the suggestions and direct recommendations of podiatrists.

Referring to the future of this institution, in his opening remarks to the first class of students, Dr. Lewi said:

It seems like a paradox that I, who have always been the exponent of higher standards in medical practice, should be officiating as the executive of a non-medical institution which is striving to educate others than licensed practitioners of medicine to practise a branch of medicine. But the contradiction is not because of my activities in this novel field. The difficulty has been that no opportunity has been vouchsafed medical students and medical practitioners to acquire the knowledge essential to practise the specialty of minor foot lesions and in consequence the public has had to accept the unscientific services available from chiropodists or to go on suffering. I promise to help in creating a center where these chiropody laymen may be educated to recognize cause and effect. This school shall be scientific—so scientific that even medical doctors, wishing to become foot specialists, may come to these halls and gain the requisite knowledge for their purposes. The standard will be raised from time to time until the medical education imparted to students will be equivalent to that received by students at regular medical schools. I am still of the opinion that no branch of medicine should be practised by those unlicensed as medical doctors, but the situation as to foot specialists is such that the existing gap must be closed so that time shall make the desirable changes which medical schools have thus far failed even to attempt, much less to accomplish.

The following sets of questions were a part of the final examinations held at the Institute, May, 1918, and will serve to convey an idea of the educational scope of its teachings:

Bacteriology and Microscopy.

1. Define gram-negative bacteria, agglutination, fine adjustment, diplococcus, hanging-drop, capsule.
2. Name the microorganisms which have been found to be the etiologic factors in the following infections: abscess, lockjaw, tuberculosis of the skin, hard chancre, typhoid, periostitis, gas gangrene, malarial fever, hydrophobia, pneumonia, ground itch.
3. Describe the tubercle bacillus and one method of staining it.
4. Discuss in detail the factors concerned in acquired immunity.
5. Describe in detail the preparation of tissues for microscopic examination.
6. Draw a picture of the specimen of hyaline cartilage shown you under the microscope.
7. Describe the difference between the two slides of (*a*) connective tissue, (*b*) spindle cell sarcoma.
8. Identify slides Nos. 1, 2 and 3.

Pathology

1. Differentiate exudate and transudate, giving example of each.
2. Define atrophy. Give the varieties of atrophy.
3. Describe the gross appearance of an ulcer in its various stages.
4. Describe the process of primary healing; of secondary healing.
5. Differentiate degeneration and infiltration. Mention some of the most common forms of each.
6. What purposes does the exuded lymph serve in the process of inflammation?
7. Of what do pus cells consist? What is leucocytosis; phagocytosis?
8. Describe the phenomena of inflammation.
9. What is gangrene; slough; necrosis?
10. Define immunity. What is the action of toxins; what is the fate of toxins?
11. How is the dead part separated from the living in moist gangrene and in dry gangrene?
12. Describe a tubercle.

Materia Medica and Therapeutics.

1. Name 5 important local anesthetics in podiatry, state how each is used, and give their mode of action (not mode of administration).
2. State physiologic action, official preparations, therapeutic uses, mode of application and poisonous effects (if any) of iodine, phenol, alcohol, iodoform.
3. Name the different baths used in podiatry, the temperature at which to be taken, effects desired in ordering them, and precautions to be observed. Describe the alternate foot bath.
4. Name six important official antiseptics used in podiatry. State in what conditions the use of each is more particularly indicated and in what manner each should he employed.
5. Define alkaloids, deodorants, purgatives, antiphlogistics, counter-irritants, astringents, antiseptics.
6. Name five caustics and escharotics; state the four ways in which they may act and tell in what manner and in what conditions they may be applied.
7. Name the different drugs and other methods which are employed in the treatment of burns and state how they should be applied.
8. When using escharotics and caustics, what precautions should be observed? What is the most important opium preparation used in podiatry and what is its formula?
9. Describe the use of Friar's balsam; Crede's ointment; liquor Burowi; Goulard's cerate; Thiersch's solution.
10. What drugs are commonly employed in the treatment of simple helomata and how should they be used?

11. Name the drugs incompatible with the use of silver nitrate; iodoform; iron.
12. How should lead nitrate be used in the treatment of onychia maligna?

Podiatry Orthopedics.

1. How does a congenital flat foot differ from an acquired flat foot?
2. Describe in detail treatment of a rigid acquired flat foot.
3. Is the restoration of normal contours in the treatment of flat foot of prime importance, or should greater stress be laid on normal functioning? Explain.
4. Does the treatment of cases of weak foot in children differ from the treatment of weak foot in adults? If so, describe wherein.
5. How does a spastic weak foot differ in actions from a flaccid weak foot?
6. Describe condition known as "strained foot". Give treatment.
7. Is Morton's toe a congenital or an acquired condition? What is the most frequent cause of Morton's toe?
8. Give the treatment of Morton's toe. Describe proper shoe, etc.
9. What is the literal meaning of the term metatarsalgia?
10. What conditions have we in mind when we speak of anterior metatarsalgia? How should this condition be treated?
11. Describe a method of making a plaster of Paris cast of the foot.
12. What exercises would you advise for weak foot; what in order to stretch a shortened gastrocnemius?

Practical Podiatry.

1. Define heloma; bromidrosis; onychia.
2. Describe in detail the treatment of infected heloma.
3. Mention and describe a bandage used for covering the great toe.
4. Describe in detail the preparation and application of shields. Mention four materials used in shielding.
5. Give etiology and pathology of onychocryptosis. Mention the various treatments for this condition.
6. Give differential diagnosis of bursitis and chimation mild. Outline course of treatment for latter condition.
7. Name five antiseptics used in podiatry and mention the strength in which each is used as such.
8. Mention four local anesthetics and describe the administration of one of them for operation upon heloma durum.
9. Mention various treatments for verruca and describe in detail any one of them.
10. When are wet dressings indicated? Describe the application of such a dressing.
11. Wherein does bromidrosis differ from hyperidrosis? Describe the treatment of the latter?
12. Describe a bandage that will cover a varicose ulcer on the lower third of the leg.

Principles of Medicine.

1. Describe an acute attack of gout of the great toe.
2. State etiology and treatment of tetanus.
3. Give prophylaxis in arthritis deformans.
4. Define and state chief diagnostic points in diabetes mellitus.
5. What would lead you to suspect scarlet fever in a convalescing patient? What prophylactic measures should be employed?
6. Define neurasthenia; Charcot's claudication.
7. Give specific treatment of malaria; diphtheria, syphilis, hydrophobia.

The fact that only six graduates out of the several hundred who have taken the examination by the State Board of Medical Examiners in this State have ever been rejected is convincing proof that their education has been such as to fit them for the work.

The practical clinical work of the students at the institute is had at clinics conducted at the school. Several years ago permission from the State Board of Charities for a license to conduct a foot dispensary was obtained, and this is now carried on conjointly with the teaching. A résumé of the activities of these clinics follows. These various departments are in active operation each night except Saturdays, Sundays and holidays.

1. A general clinic wherein are treated general excrescences commonly arising on the feet.
2. An orthopedic clinic where are treated all foot cases involving bone and muscle deviations from normal; also the preparation of plaster of Paris dressings, strappings, casts, foot braces, etc.
3. A special clinic where unusual conditions are treated, including serious cases of onychocryptosis, verrucae, infections, etc.
4. Orthopedic massage department for the massage of the lower extremities.
5. Special massage department where massage is done with a view to correcting muscle contractions, posture defects, etc.
6. Thermotherapy department.
7. An *x*-ray department.

In each of the above departments, a precise system of record taking is in operation. A complete history of every case is on file embracing all features of the diagnosis and treatment, thus making these files a valuable repository of data for future study and scientific education. The average number of cases treated annually since 1913 is 10,000. Some very valuable work is also being done in research relating to such topics as focal infection, gait, posture, etc.

The foregoing recital of the history of podiatry in this State is interesting as, except for New Jersey, it was the only State for many years where podiatry was recognized. At the present time, there are twenty-three States regulating podiatry as follows: New York, New Jersey, California, Washington, Colorado, Nebraska, Minnesota, Wisconsin, Michigan, Illinois, Louisiana, Ohio, Virginia, West Virginia, Pennsylvania, North Carolina, Connecticut, Massachusetts, New Hampshire, Vermont, Maryland, Rhode Island, and the District of Columbia. All of the other States will probably legislate similarly along podiatry lines within the next three years.

Since the establishment in this State of the First Institute of Podiatry, the following institutions have come into existence whose officials claim equal distinction in their efforts to train podiatrists: The California College of Chiropody at San Francisco; the Illinois College of Chiropody in Chicago; the Ohio College of Chiropody in Cleveland; the Temple University of Philadelphia, which has a department of chiropody and is educating podiatrists in conjunction with its medical course. The latest addition to podiatry teaching institutions is the University of Massachusetts in East Cambridge, Mass.

Podiatry teaching schools have made rapid progress. They are now crowding into nine months, averaging nine hours of daily application, the equivalent of two years of medical training. In another year, the course will probably be of two years duration, encompassing fully three years of medicine, and in 1921, there will possibly be a three years course, tantamount to a full medical school course, minus major surgery in its special

applications. Ultimately, the First Institute of Podiatry will be merged with some one of the existing universities, whereupon the special subjects now there taught will be incorporated in the medical curriculum thus terminating the occasion for its existence, or it will ask and doubtless secure a charter of its own to educate medical students and to graduate them, plus the privilege of instruction in post-graduate work. It is up to the medical schools to determine the issue. If they were to commence next year to establish limited courses for educating podiatrists and, additionally, post-graduate schools were to establish departments for specializing on foot care and foot treatment, most of the podiatry schools would surrender their charters and thus, after all of these centuries, the care of this class of cases would fall into medical hands, scientifically equipped properly to care for them and to provide for the public foot wants.

There were those who jeered at the pioneers in this attempt to elevate chiropody from a trade into a profession. They ridiculed the men who were at the helm in this undertaking and who were charged with being commercialists. The scoffers have remained to pray! There was never a more altruistic proposition launched by the ethical in any profession. Every cent of money realized from tuition fees, and that was the only source of revenue, was expended with a view to bettering the New York institution. For years all of the faculty served without pay—in fact the majority of them received pay for only one brief term, the full-fledged professors commanding the high (?) salary of three dollars per hour. The war took seven men from the faculty to the front and with them went scores of students. The Institute did not close, but under the same management, with its lessened forces, kept on with its educational efforts and the attenuated faculty has continued functioning without thought of monied recompense.

As to the original Pedic Society of this State, the excellent results from its activities encouraged the organization of similar bodies throughout the country. There are now thirty-seven States having such societies, and it is safe to predict that within a few years, such an organization will exist in every State of the Union. Cooperating with these State bodies is the National Association of Chiropodists, which has done valuable work in advancing curricula, advocating the passage of the army service bill, and obtaining a wider scope of endeavor for practitioners. In some States, at present, the law permits the podiatrist to perform operations of a major nature while in other, practice is limited to external structures. It is, however, safe to predict that very shortly, every State in the Union will have enacted legislation regulating podiatry and its scope. The tendency is now to grant a wider range of activity to the podiatrist but there is no desire on the part of the podiatrist to be equipped with the authority of the orthopedist.

An interesting phase of the history of the profession obtains in the fight that was made to obtain official recognition in the army for podiatrists. In 1917, the activities of the National Association herein culminated in the appearance of Dr. Lewi, of New York, Dr. Siemon of Ohio, and Dr. Harlan of Maryland, together with the special army service committee of the association which was headed by Drs. Burnett and Stanaback, before the Surgeon General of the United States Army and also before the Committee on Military Affairs of the House of Representatives, and here their arguments, though not achieving the desired object, resulted in a concession from the Medical Corps Committee (Mayo, Brackett, and Silver) that there was urgent need of the service even though they did not recommend a commission to these practitioners.

As to the literature on foot lesions, very little of scientific value can be discovered prior to the 18th century. Then, about 1800, a Dr. Lion gives an account in one of his books of his efforts to elevate chiropody as a profession. His writings have an historical significance in that they reveal the curious fact that it was considered undignified to treat feet. This notion, whatever its source, seems to have persisted and may be responsible for the neglect accorded this branch of medicine. Dr. Lion applied in 1796 to the College of Physicians and Surgeons for a diploma with the intention of treating feet only. In spite of receiving high honors in his studies, his license was refused because he was engaged in the degrading "business of corn cutting." This was followed by a similar rejection from another institution because he was engaged in practising on feet.

As to other works, the earliest treaties on the nail appeared in 1646. The earliest American treatise on chiropody appeared in 1862 entitled "Surgical and Practical Observations on Diseases of the Human Foot." The earliest manifestation, however, along the lines of progress in the development of scientific literature was the production here of the "Text Book of Chiropody" containing 1183 pages and which represented the first scientific attempt to collect important and valuable foot data into one book. This volume was issued about 1914. Subsequent to this the appearance of newer works was so rapid and comprehensive that, compared with the newer literature, this volume is becoming a curiosity of early literary endeavor. However it was hungrily devoured all over the world and finally through the efforts of two important organs, *The Pedic Items* and *The Podiatrist*, which encouraged the publication of foot articles by physicians and podiatrists, a wealth of new material was added, tried, and developed.

Already, there have been issued as part of a contemplated system of podiatry text books to appear in sequence, "Surgery With Special Reference to Podiatry," by Drs. Stern and Adams; "The Text Book of Practical Podiatry," by Drs. Joseph, Burnett, and Gross. Dr. Lewi is the editor of all three of these publications.

It seems appropriate to close this narrative with a quotation that reveals the depth of purpose and earnestness, the scientific aspiration, and the eloquent idealism that has actuated and resulted in the evolution of podiatry:

> The beauties of the human foot, coupled with its strength to perform the functions for which it was

created, caused the ancient Greeks to glorify it in song and in art. Medically and surgically, it has always been a negligible factor in the world of science, notwithstanding the burdens which it is made to bear and in spite of the interference with locomotion and with general health which its non-care has occasioned for all centuries since creation. Our propaganda recognizes the importance of this part of the anatomy and is causing the race to realize the need for footcare in health and for scientific foot treatment in disease.

AMBULATORY SKULL FRACTURE WITH DELAYED SYMPTOMS.

A CASE REPORT.

By KARL A. MENNINGER, M.S., M.D.,

TOPEKA, KANSAS.

ASSISTANT IN NEUROPATHOLOGY, HARVARD MEDICAL SCHOOL; ASSISTANT IN NEUROLOGY, TUFTS MEDICAL SCHOOL.

The manifestations of skull fracture are proverbially multiform, and the accretion of our data on the matter will surely be materially strengthened when the war literature is completely assembled.

It is probably not infrequent that cases of skull fracture are discharged undiagnosticated even from hospitals with the best of facilities. It is rather unusual, however, for such a case to be diagnosticated later from symptoms that appear prominently only some time after the trauma.

The following is such an instance. It is deemed worthy of report, first because of the intrinsic interest in this type of case, and secondly because of the numerous points of incidental interest connected with it.

A man of 34, weighing over 200 pounds and in excellent physical condition, wrestled with a friend one evening on the way home from work, and evidently fell with considerable force upon the walk. He was picked up quite unconscious and taken to a general hospital, where adequate medical attention is available. He remained unconscious for 32 hours. *X*-rays of the skull were taken, but they were apparently negative, as nothing was said to the patient or his wife about a fracture and he was allowed to go home 4 days later.

Because of insomnia, amnesia for the events connected with his fall, "loss of power to think of things," severe headache, dulness, and a certain difficulty in speaking, he consulted a physician, who recommended him to the Boston Psychopathic Hospital Out-Patient Department.

He reported here just two weeks from the date of the injury. At that time he presented the following symptoms:

Subjective: Headache and mild dizziness; difficulty in finding words and collecting thoughts.

Objective: Slight motor aphasia, without agraphia, astereognosis, ataxia, or other neurological phenomena; slight bewilderment, irritability, and obstinacy; complete negative physical examination.

An *x*-ray and ophthalmoscopic examination were made, the latter revealing a left-sided optic neuritis of severe grade, and dubious choking of the disk. The *x*-ray report which came in later showed an extensive linear crack extending from the left temporal to the occipital region.

He was sent to the Peter Bent Brigham Hospital for observation and treatment and I am indebted to them for the following additional data:

Further Findings: Loss of sense of smell and taste; visual acuity and perimetric fields normal despite unilateral (left) moderate choked disc; contraction of left pupil; clear spinal fluid.

They considered that there was no indication for surgical intervention. After 3 days the choked disc and aphasia had practically entirely disappeared, and a week later he was discharged to the Out-Patient Department.

In this case there were, as usual, the two inseparable sets of symptoms and signs, those which are characteristic and should have made the diagnosis, and those which are unusual and add to the interest of the case.

The clearly diagnostic points were:

History of trauma; initial unconsciousness, with subsequent amnesia; persistent headache and dizziness; difficulty in thought processes; moderate aphasia, with loss of taste and smell; unilateral optic neuritis with moderate choking; *x*-ray revelation.

The unusual features present were:

The latent period, with a diagnosis first made on the patient when ambulatory, and 2 weeks after the trauma; the sudden subsidence of symptoms after this late appearance; failure of the first *x*-ray to reveal the crack; delinquency of the first hospital in discharging the patient unwarned; absence of diminution in visual acuity or perimetric fields.

Mulvane Building.

TWO UNUSUAL CASES OF ALCOHOLISM.

By LUCIUS FELIX HERZ, PH.B., M.D.,

NEW YORK.

1ST LIEUTENANT U. S. O. R. CORPS, ASSISTANT SURGEON N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The following cases of alcoholism, one acute, the other chronic, seem to me to be of sufficient interest to be recorded.

DELIRIUM TREMENS AFTER A SINGLE DRINK.

K. H., a girl of twenty-one, was seen by me recently during a violent attack of as typical delirium tremens as one is apt to meet. History revealed a negative alcoholic history, except for a very occasional drink of beer. She had never before in her life partaken of anything stronger than this, but the evening I was called to see her she had complained of dysmenorrhea and a friend had given her a single drink of gin. About an hour later she had a violent attack of delirium tremens, with loss of all comprehension of her surroundings. She flung herself about violently, fought with all present, had violent tremors, tore her clothing and her hair, and even bit herself. Half an hour later she had a lucid interval of about ten minutes, and then another similar attack of delirium.

After a hypodermic of morphine, gr. ¼, combined with hyoscine gr. 1/100, she seemed to be temporarily more excited, but half an hour later calmed down again and the convulsions did not recur.

I report the case as a very unusual one, in view of the negative alcoholic history, and negative history for epilepsy and any other nervous affliction.

MARKED DYPSOMANIA WITH APPARENT CURE.

K. L. I., a young married woman of twenty-five, was first seen by me on March 22, 1918, when I found her suffering markedly from the effects of an alcoholic debauch. I gave her a hypodermic of morphine and atropine to allay her extreme nervous state, and ordered chloretone, gr. x, at bedtime for future use.

She gave a history of five years of intermittent sprees, during which she would take a quart of whiskey or gin in a day and frequently take a tumblerful at a single draft. She claims that her first drink awakened an ungovernable desire for more, and she drank to excess the first time she ever took a drink. These sprees would be indulged in at intervals varying from one to three months, and would last for about a week. She derived no pleasure from drink, she claimed, but stated that it took away a feeling of marked depression that she had otherwise preceding her sprees. Patient also smoked about twenty cigarettes per day. She had had the Towns treatment twice without any appreciable improvement.

Physical examination revealed a rather marked fine tremor of the fingers. The chest showed harsh breathing and numerous fine subcrepitant râles of the right infraclavicular fossa, with increased fremitus and whispered broncophagny. Sputum was negative for tubercle bacilli.

An *x*-ray of the chest, taken at the Post-Graduate Hospital, showed a chronic healed tuberculous process of the left axilla, with congestion of the left hilum, enlargement of the bronchial lymph nodes, and congestion of the left apex, suggesting a tuberculous process. This process on the left was in contradistinction to the physical signs on the right, and later developments proved that there was no active tuberculosis whatever, but merely an old healed process, with an acute bronchitis. The bronchitis was treated with a prescription calling for a mixture of ammonium chloride, syrup of ipecac, and codeine, and promptly responded to treatment.

A consultation was held with Dr. Arthur F. Chace, who regarded the tuberculous process as probably latent, and advised active treatment for the drink habit as the primary object to be attained.

The patient first went away for a rest, to restore her shattered nervous system, and was not again seen by me until July 31, when she was found again after an alcoholic debauch and just as badly off as when first seen. She was given a hypodermic of morphine and atropine, and later a prescription for chloral and bromides. Active treatment in an institution was again advised.

Two days later the patient consented to undergo a course of treatment and was admitted as a private patient of the writer's at the New York Post-Graduate Hospital. Owing to two previous unsuccessful treatments, it was determined to use the Stokes treatment. This consists in a single dose of morphine, followed by hypodermics of eserine and pilocarpine every two and a half to three hours, the eserine being discontinued when the bowels move. The dose of pilocarpine is usually gr. $\frac{1}{15}$. The treatment is continued for three days.

The patient took the treatment well, perspired freely, and was greatly salivated, as would be expected, but mentally and physically in good condition. The craving for liquor lasted until the second hypodermic, and did not occur since.

Following the treatment, the patient was given a mixture of chloral and bromides for sleeplessness, and a tonic consisting of iron, arsenic, and strychnine in pill form, to avoid the alcohol of tinctures. The patient rapidly regained her strength and up to the present, over eight months since the treatment, she has not relapsed. Of course I had impressed upon her the importance of exercising her own will power in the future. Without this, no treatment in the world could be successful.

251 West 45th Street.

Medicolegal Notes.

Payment for Hospital Services.—In an action by a hospital against a former patient to recover for board and treatment it appeared that the defendant was injured July 17, 1916, while in the employ of F. & Son, from whom he subsequently recovered damages for the injury. At the time the defendant was taken to a physician by F. & Son, from whose office the physician by telephone obtained permission to remove him to the plaintiff hospital. The defendant understood the hospital was to be paid by F. & Son. The plaintiff's officers did not know the defendant was brought to the hospital by consent of F. & Son, and opened a ledger account against him. When the defendant left the hospital the plaintiff asked him who was to pay for his treatment, and when he replied F. & Son, they made a memorandum to that effect on the ledger account. The plaintiff made no demand for or claim of payment upon the defendant, except by bringing the suit November 15, 1917, which was after the trial of the defendant's suit against F. & Son, which was submitted to the jury upon the theory that the hospital had no claim against the injured man. Upon these facts the municipal court ordered judgment for the plaintiff and the defendant excepted.

The New Hampshire Supreme Court holds that benefit received by the defendant from the plaintiff's treatment, if in fact the treatment was beneficial, a fact not found, does not establish the legal duty of payment. The action was in assumpsit, to recover damages for the breach of the defendant's promise to pay. To authorize a verdict against him this promise must be found as a fact. Such fact may be found from an express promise of payment or from facts and circumstances from which a mutual understanding that payment was to be made may be inferred; or the circumstances may be such that it would be inequitable to permit the defendant to deny the promise. The contract may be express, tacit, or created by estoppel. There was no express promise to pay. It did not appear that either party understood the service was to be furnished gratuitously. Hence it could be found that the defendant knowingly accepted service from the plaintiff, burdensome to it if not beneficial to him, for which it expected payment. From this an understanding or promise to make the expected payment could, and perhaps must, be found.

The defendant's understanding that the hospital was to be paid by F. & Son was not necessarily inconsistent with a promise on his part to pay if they did not, or if the hospital did not render the service upon the credit of F. & Son. If the defendant accepted the service understanding that in no event was he to be liable therefor, his negligent or intentional concealment of such understanding from the plaintiff was evidence upon which it could be found that he was now estopped to deny his promise to pay which under the circumstances would ordinarily be inferred from his acceptance without objection of valuable services, rendered with expectation of payment.

If the defendant's promise were found on either ground the question remained whether the plaintiff was estopped by its apparent acquiescence in the defendant's claim that F. & Son, and not he, were to make payment until after he had changed his position in reliance thereon, if it knew, or ought to have known, he would do so. Whether the defendant promised to pay or was estopped to deny such promise, and whether the plaintiff was estopped now to assert such promise were held questions of fact to be found from the evidence. The verdict would be found as these facts should be determined, and judgment would follow the verdict. —Elliot Hospital v. Turcotte, New Hampshire Supreme Court, 105 Atl. 361.

Agreement to Pay Physician's Salary.—The Texas Court of Civil Appeals holds that it was not against public policy, under the state Workmen's Compensation Act, for an employer to agree to pay a doctor's salary, the employer to retain the medical fees allowed by the insurance association. If it were against public policy, a physician entering into such a contract, it is held, is *in pari delicto* and cannot sue the employer for such fees, where he has received and retained his salary, since he cannot affirm in part and repudiate in part.—Sherrill v. Union Lumber Co., (Tex.) 207 S. W. 149.

Extent of Medical Testimony.—In an action for personal injury caused by a fall on the street the attending physicians testified as to the extent of the injury. They had made an examination of the plaintiff without the help of an *x*-ray instrument and had each testified to his diagnosis. It appeared, also, that some time subsequently an *x*-ray photograph had been taken by some one else. On cross-examination each testified in substance that he was confirmed in his diagnosis by the *x*-ray photograph. Although the defendant was entitled to have the opinion of the witness confined to his own examination, the error, if any, in admitting reference to the *x*-ray photograph, was held not prejudicial. The injury, a dislocation of the iliosacral joint, was a serious one. The plaintiff suffered much and spent a considerable time in a hospital. He had not recovered at the time of the trial, nearly a year after the accident. The verdict was for $2,500. It was held that the moderation of it was strong evidence that the jury were not unduly influenced by the evidence complained of.—Hearn v. Waterloo, Iowa Supreme Court, 169 N. W. 392.

Medical and Surgical Lessons of the War.

VENEREAL PROBLEMS OF THE WAR.

By VICTOR COX PEDERSEN, A.M., M.D., F.A.C.S.,

NEW YORK.

MAJOR, MEDICAL OFFICERS RESERVE CORPS, UNITED STATES ARMY; MEMBER OF THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES, OF THE AMERICAN UROLOGICAL ASSOCIATION, AND OF THE COMMITTEE ON VENEREAL DISEASES OF THE ADVISORY COUNCIL OF THE DEPARTMENT OF HEALTH OF NEW YORK CITY; VISITING UROLOGIST TO ST. MARK'S HOSPITAL; RECENTLY MAJOR, MEDICAL CORPS, UNITED STATES ARMY.

IN preparing this paper two aims have been held. These are to present a reasonably complete review of the work planned by the Government and its results and to forecast the outlook of the future in terms of the gains made during the campaign in all arms of the military service, in civil communities as wholes, and in industrial interests as individual fields.

The general paper therefore subdivides itself into three general headings: the governmental work, the immediate results and the industrial field.

It is hoped that the last feature will be of especial interest because, unless the work so well begun is equally well continued, much economic loss to the business world through venereal disease will continue rather than be more or less checked. Like every other problem of human society arising from human weakness venereal diseases have always been with the race and always will remain with the race. If the ideal is reached that the young shall be instructed in the normal physiology of sex in a high minded way and concerning venereal disease depredations in a dignified and truthful way, and that the civil community shall realize that ignorance and innocence are not synonyms and that indifference and silence are the prices of untold losses then much will have been accomplished. After such a goal no one may say "I did not know."

Hallam in "Three Great Army Records" * makes the statements that: "In the Russo-Japanese war the Japanese army went eighteen months without having an immoral woman in the army. After they had gained their victories and were lodged in comparative safety in Mukden, for a period of two or three months, there were sixty immoral women permitted in the neighborhood of the army. The authority for this statement is a book published by a French army officer, Dr. J. J. Matignon, ex-Attaché of the French Legation at Peking, Major in the Medical Corps, French Colonial Army, who was officially attached to the second Japanese army during the Russo-Japanese war. His statement in regard to it is as follows:

" 'The campaign of the Japanese in Manchuria can be cited as a model of its kind. Never has history recorded a war in which the rate of mortality has been brought down to such a low figure for a like duration of campaign. This war must be considered as a triumph of military hygiene. . . . This question of hygiene and sanitary police leads me to speak of prostitution and its regulation. The Japanese army waged a war which lasted eighteen months without a woman. It is a fact perhaps unique in history. . . . The little manual of hygiene was very explicit on the subject of venereal diseases: "The prostitutes in China and in Korea are for the most part infected. Therefore, avoid them; thus the world will not know your shame and your children will not suffer." ' "

The foregoing statement by Hallam is probably correct, but I have not been able to verify the fact that the Japanese were indeed the first to institute in a methodical manner the present handling of the venereal question in military circles. According to a personal letter to the writer from the office of the Surgeon General of the United States Army, verification from the records thereof is also impossible.

The problem is the historic depredations of venereal disease among soldiers and sailors through "camp following" by unproductive members of society typified by prostitutes, liquor dealers, and gamblers. The Japanese Army in the Russo-Japanese war may have been the first to develop the present venereal disease prophylaxis and regulation and discipline of infected enlisted men.

Active propaganda against venereal disease began in our army in 1909, according to the report of the Surgeon General, 1918. It is interesting to abbreviate reports of that period. The evil, the lost efficiency and humanitarian considerations induced several military posts to attempt prevention. Such steps were instruction of soldiers by lectures (on the dangers of venereal disease and the healthfulness of continence), regular inspections and treatment, withdrawal of passes of the infected and prophylactic medicines and instructions on request of individuals. Such methods to reach each recruit on admission were expected to reduce the evil record of the United States Army. This brief campaign was followed by longer discussions in the Surgeon General's report of 1910, with the following points: The venereal peril outweighs all other sanitary questions. Optimism and prudery do not excuse honest consideration. These diseases are not beyond preventive medicine. Most sociologists and sanitarians believe that the evil is social and must be reached by public discussion and education in sexual and venereal matters. A number of state and municipal health authorities and private societies publish and distribute literature. The War Department cannot do better than follow this example and ignore narrow adverse criticism.

Reports since the Spanish-American War showed increase in the admission rate from 84.59 per 1,000 in 1897 to 196.99 per 1,000. These figures exceeded those in European armies as follows:

British (at home 68.4)	75.8
Austro-Hungarian	54.2
French (at home)	34.8
Prussian	18.7
Bavarian	15.2

Among successful measures in other services for control of venereal disease are the following: (1) recreation in clubs, etc., attracting men away from vile resorts; (2) temperance associations to avoid the relation between alcoholic and sexual indulgence; (3) periodical examination for detection of venereal disease; (4) treatment until cured; venereal registers being kept until the man is cured, and transferred with him from point to point as necessary; (5) formal and informal instruction on the nature, extent, and perils of venereal disease. In-

[1]Published by the Illinois Vigilance Association.

struction that intercourse is not essential to mental or physical vigor and health; (6) approved measures of prophylaxis for the incontinent.

After several years certain measures of prevention were recommended, such as a law by Congress stopping the pay of all men incapacitated by venereal disease. A definite course of procedure at every post was laid down, and men disobeying orders for personal prophylaxis were to be punished. This law of Congress was published in General Orders No. 31, W.D., 1912, and certain compulsory measures with punishment for disobedience were published in General Orders No. 17, W. D., 1912.

"During all these years, however, the medical authorities were greatly hampered on account of their inability to control the neighborhoods surrounding military posts. Also the difficulty of controlling alcoholic indulgence by the men while away from military posts made the problem much more difficult."

These two great problems by proper solution led to proper handling of the question in this war.

My own experience with venereal disease in the first draft was interesting and peculiar. I volunteered as Consulting Physician to the Selective Service Headquarters of New York State in New York City in July, 1917, and remained on duty until November, 1918, when I went into the service as Major of the Medical Corps for assignment to one of the proposed venereal infirmaries. I knew that the policy of the Army up to 1916 had been rejection of active venereals but the regulations for physical examination of registrants were not so definite. When examinations began inquiries of the Surgeon General's office were so numerous and largely needless that no further inquiries were answered. The director of the draft, Lieutenant Colonel Roscoe S. Conkling, U. S. A., and I decided that the previous policy of the army was doubtless the intention of the draft and proceeded to exclude venereal cases in infectious stages. This decision led the writer to open his clinic at St. Mark's Hospital for special examinations. This incident was the suggestive experience which led to the Medical Advisory Boards later in the draft. In this way, I examined perhaps 1,500 cases chiefly of venereal disease, and not until December, 1917, while at the office of the Surgeon General, did I learn that registrants were to be accepted, if not incapacitated by venereal disease, to be properly treated before induction and to be left to camp medical officers for final acceptance or rejection.

Section 11 of the Selective Service Regulations was another stumbling block because it forbade in letter and spirit Local Boards to cooperate with State and Municipal Boards of Health by reporting infectious diseases discovered during examinations for the draft. Of particular interest to the Commissioner of Health in this city was tuberculosis and I remember an interview in the office of the Provost Marshal General appealing for the right of Boards to report these cases to the health authorities. Of course there were many other similar appeals and this right was finally granted to boards by special order.

I further argued that venereal diseases be made reportable also, in which the Honorable Martin Conboy, in charge in New York City, and Major F. S. Hutchinson, in charge in New York State, concurred. The Government finally heeded these and many similar protests and made venereal diseases reportable in all states so providing by statute or sanitary regulations. Note 7, Selective Service Regulations, Second Edition, states: "This section does not relieve examining physicians of their legal duty to report to local health authorities cases of communicable disease which come under their notice when such report is required by State law."

In the United States Service the incidence of venereal disease is suggested by the following data. The annual report of the Surgeon General, U. S. N., 1918, states that venereal rejections for reenlistment are 0.5 per cent., whereas those for enlistment are 1.5 per cent, a ratio of 3 to 1 in favor of the trained man.

The Navy began fifteen years ago with prophylaxis and has steadily broadened its policy into well rounded prevention and control of venereal disease with increasing attention to moral and educational problems.

One suggestion, respectfully made to the Medical Department of the Army and the Navy, is that all regulations should be uniform for the sake of consistent statistics and reliable deductions. One of the most important is an order in both services requiring regular physical examination of the men such as is now the rule in the Army. The writer has been told on highest authority that in several naval stations such examinations are far less frequent regular and searching, and that therefore, many of the Navy statistics are not as reliable as those of the Army. Naval statistics, however, (without subdivision into recent and old cases or preenlistment and postenlistment cases) are published as 165 per 1,000 for eight years preceding the war; 99 per 1,000 from July 1, 1917 to July 1, 1918, and 70 per 1,000 from July 1, 1918 to October 1, 1918. Like the record of the Army, this is progressively creditable.

The second report of the Provost Marshal General, to December 20, 1918, Table 60, shows that of total rejections by Local Boards and camp surgeons, 467,694, 1.33 per cent. were for venereal disease, and that of 40,382 (included in the first total), discharged from the army after acceptance by Local Boards and Camp Surgeons, 3.59 per cent. were for venereal disease. There is, of course, no index in these figures of the number of venereals, old and new, accepted in a similar number of inductions during the same period of the draft. *The same limitation and uncertainty apply to all other statistics unless otherwise indicated. Such defects in the records are unfortunate and irremovable.* In his report for the first draft, Table 15, of 10,258 physical rejections, 4.27 per cent. were for venereal disease. This figure corresponds with the opinion which the writer has had through nearly 20 years of specialization, that nearly 5 per cent. of the male population is at all times infected with one or another kind and degree of venereal lesion.

According to the 1918 report of the Surgeon General, U. S. N., these lesions in 1909 ran 191.71 to the thousand, steadily declining to 88.71 in 1917 and rising to 105.77 in 1918. The statement stands unchallenged that there are five times as much

venereal disease in the service acquired before induction in civilian life as after enlistment. During the war more than 3,200,000 days of service were lost by men while surgeons were taken from the honorably ill and wounded for their treatment. Early in the war the cost of new cases during one period of six weeks was greater than the maintenance of one camp of 21,000 men. In one section of Europe 17,000 cases were concentrated. One of our Allies at that time had more soldiers in hospitals from venereal disease than from wounds. The Surgeon General, U. S. A., has had weekly venereal reports beginning August 30th, 1918, from the following camps: Dix, Meade, Lee, Pike, Upton, Devens, Shelby, Sheridan, Wheeler, and Greene. Tabulations up to January 31, 1919, show annual rates per thousand troops as follows:

For total cases reported	217.50
For before enlistment cases	205.90
For after enlistment cases	11.38
Prophylactic treatments given	226.34

Compilations from the first five camps from March 29, 1918, to January 31, 1919, 45 weeks, result; cases before enlistment, 294.40, and cases after enlistment 10.17 per thousand *average*. Irregular reports from other camps indicate that this low after enlistment record may not apply for the whole country, but conservatively the rate per thousand will hardly average over 15 or 20. This means nearly 75 per cent. reduction from the rate of 1916 of 91 per thousand, when the cases were practically all new infections because recruits with venereal infections were rejected at that time. Fig. 1 shows these statistics graphically.

Correlated with this is the statement by Additon that of 177 illegitimate births in camp cities in only 84 were soldiers or sailors responsible.

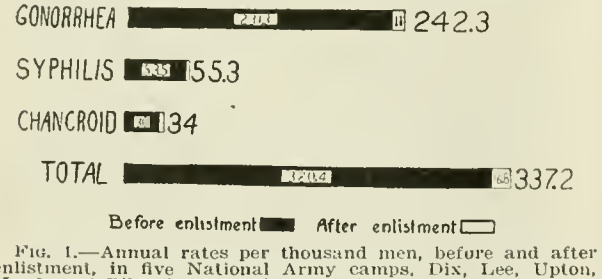

Fig. 1.—Annual rates per thousand men, before and after enlistment, in five National Army camps, Dix, Lee, Upton, Meade and Pike, for gonorrhea, syphilis, chancroid, and total venereal disease, based on thirty-seven special weekly reports from March 29 to May 24, inclusive.

Control of venereal disease among the enlisted men was greatly promoted by the aid of national and local health authorities, the stoppage of alcohol, excellent public health supervision in extra-cantonment zones and the interest of civilian organizations and communities.

Cooperation by the Department of Health, of New York City, is indicated by the statement of Harris.[1] Up to the beginning of 1919 the Advisory Clinic had served 13,534 persons with reliable records: males, 12,582, and females, 942; unmarried, 9,340; married, 2,642. Syphilis affected, 4,373; gonorrhea, 5,059; neuroses, 1,203, and nonvenereals, 3,277. As this service continued from 1914 to 1918, it covered the entire period of the war and more. Not the least of its benefits was prevention of consultation of quacks by the unfortunate patients.

Within the army itself the office of the Surgeon-General appointed a Special Advisory Committee, who prepared and circulated the following plan of attack on the venereal problem, summarized under four headings:

A. Social measures to diminish sexual temptations.

(1) Especially repression of prostitution and the liquor traffic.

(2) The provision of proper social surroundings and recreation both within and without the military establishments.

B. Education of soldiers and civilians in regard to venereal diseases and the normal hazards related thereto.

(1) For soldiers through official lectures, pamphlets, exhibits, motion pictures and correlated educational work of the chaplains and representatives of religious and social agencies under the supervision of the Commission on Training Camp Activities.

(2) For civilians through encouragement and assistance to professional, business, commercial, religious, men's and women's organizations and social-welfare associations.

C. Early treatment (or prophylactic measures) against venereal diseases.

(1) Through treatment stations established in regimental infirmaries and in cities accessible to large numbers of troops.

(2) Through follow-up measures adapted to individual cases to discourage subsequent exposures to infection.

D. Medical care of those infected.

(1) Through hospitalization of all cases requiring such action for the best interests of the patient, for shortening of the non-effective period, and for the protection of the other soldiers.

(2) Dispensary treatment and follow-up supervision for those who do not require admission to or further detention in the hospital.

Correlation of the four major activities was aimed at with laboratory, sanitary inspection, hospital and reconstruction divisions of the Medical Department and with the recreation, law enforcement, education and clinic activities of the Commission on Training Camp Activities and the United States Public Health Service. In brief, the aims were: (1) Protection of the drafted men at home before induction and while traveling; and (2) Protection of the soldier at all times in service and until mustered out.

The following program in civil communities was directed by the Division of Venereal Diseases of the United States Public Health Service in the interests of (1) soldiers and sailors; (2) registrants constituting the reserve army; and (3) industrial and agricultural workers.

The program laid down the following details: (A) Cooperation of State and Municipal Boards of Health; (B) Medical measures including (1) extra-cantonment clinics, (2) treatment of persons controlled by the Federal Government, (3) medical officers in detention homes, (4) free arsphenamine;

[1] *New York Medical Journal*, March 29, 1919.

(C) Educational activities embracing (1) national organizations, (2) industries, (3) quackery, (4) academic emergency measures, (5) nonacademic emergency measures, (6) school curricula, (7) statistics, (8) law enforcement, (9) production, (10) cooperation with Boards of Health and State Councils of Defense; (D) women's work, under the Section of Women's Work of the Commission on Training Camp Activities.

Conservation and coordination were secured by the Interdepartmental Social Hygiene Board, comprising the Secretaries of War, Navy, and Treasury, Lieutenant-Colonel W. F. Snow representing the Surgeon-General, U. S. A.; Lieutenant-Commander J. R. Phelps representing the Surgeon-General, U. S. N.; Assistant Surgeon-General C. C. Pierce representing the Surgeon-General, U. S. P. H. S., and in charge of the Division of Venereal Diseases. The Army Appropriation Act, included in the Chamberlain-Kahn Bill, created this board with the important functions in the combat of venereal disease. This act appropriated $100,000 annually for two years to be paid for scientific research and discovery of more effective medical prevention and treatment of venereal disease. This act appropriated $300,000 annually for two years for discovery and development of educational prevention of venereal disease and for sociological and psychological researches. This board is to select institutions for these activities.

American efficiency was evoked by frank statement of the problem in its military and civilian relations. Nothing in the war shows greater willingess to hear, heed, dare, and do than this venereal disease question. Every possible effort was to protect the manhood and promote the manpower of the nation exemplified in the activities of the Commission on Training Camp Activities. By recreational and educational environment in camps, respite was given from the trials of training as substitutes for the respite of ties left behind in family, friendships, social organizations (such as churches, colleges, clubs, and the like), athletic sports, theaters and libraries. Physiological importance was recognized of training on one side and on the other side contentment of mind and body. The general principle was that severity of military training must have a period of rest and recreation. If the prostitute and the saloon were to be repressed, something must be put into their places as diversions. Idleness is always fruitful of temptation and idle time must be filled with instruction, sports and dignified social relations.

In strict accordance with this dictum concerning men it has been noted that the policy of recreation and entertainment for women operates in keeping many in the paths of decorum. In other words, like the physiology, the mentality of sex is alike in both men and women. The onus of idleness in this matter was proved to me by a physician in the mountains of New England. After he had delivered about 500 women, he stated that in the towns 10 per cent., and in the outlying districts fully 30 per cent. of the births were either illegitimate or within "hasty marriages." He explained this condition by the idleness of the boys and girls of the hillsides after working hours, as compared with the entertainments possible for the town people.

The suppression of alcohol was seen to be a very important thing on account of the association of drunkenness and venereal diseases, and of the business affiliation between the saloon keeper and the brothel keeper. These are often the same person.

Of the four major topics previously stated, each deserves brief individual consideration. Social measures to diminish sexual temptations include suppression of prostitution and liquor traffic and provision of proper surroundings and recreation. Prostitution and liquor traffic must be observed and suppressed in camp zones and surrounding districts, cities and towns whither soldiers go or through which they travel. Military and civil authorities have been co-ordinated through the Commission on Training Camp Activities. Volunteer organizations have reported failures, indifference and abuses and have otherwise served in law enforcement. Outside camp zones many factors have operated, such as State Councils of National Defense, Civil Police and Health Boards, Associations of Commerce, Women's Clubs, other social and religious bodies, and newspapers.

Social measures for recreation and entertainment in camps and adjoining zones stimulated social relations and pastimes, established centers of fellowship and rest for soldiers, and opened responsible and respectable rooms for soldiers to meet their female relatives and friends. Women police patrols and exclusion of women from soldiers' tents, quarters, and camps were provided and attention was given to rooms for reading, lectures, music, games, friendly intercourse, and hobbies, through the Young Men's Christian Association, the Young Women's Christian Association, Knights of Columbus, Jewish Welfare Board, Salvation Army, Playground and Recreation Association, American Social Hygiene Association, churches and similar bodies.

Outside of zones the same policy was followed to keep districts visited by soldiers as clean as possible. Diversions and amusements and wholesome places were provided for the soldiers through inexpensive Service Clubs, associations of men and women for meeting, informing and directing soldiers in towns and railway junctions and large cities. Civil authorities suppressed vicious amusements and cleaned parks and recreation places through morals police, female officers, and vigilant societies. The Federal Government undertook inspection of all conditions in camps, zones and annexa, through its own officials and responsible civic bodies.

Education of soldiers and civilians was far-reaching. Lectures to soldiers were given by medical and line officers and competent volunteers from other organizations. The lectures emphasized self-control, dwelt on the dangers and depredations of venereal disease, and indorsed the Government program. Pamphlets against venereal disease and instructions for prophylaxis at regimental infirmaries were used. Local Exemption Boards in many cases supplied these pamphlets. Exhibits were of value containing placards, motion pictures, stereomotograph transparencies and the like. In the civil community, a parallel educational movement was instituted. Authority and influence of the military authorities were behind private organizations in the common sense of this program. One of the most important steps was frank and valid instruction of

women concerning venereal diseases through such avenues of the General Federation of Women's Clubs, Patriotic Women's League, the Young Women's Christian Association, and the Women's Christian Temperance Union.

The foregoing is the general, social preventive effort to reach the enlisted man before infection. Any program would be defective which was without attention to the man who, notwithstanding all educational and other effort, indulged in sexual gratification and incurred the direct risk of disease.

The program, therefore, included prophylactic measures embodying instruction, and application. Enlisted men were taught the value and limitations of prophylaxis in furnishing imperfect protection and never complete safety. In regimental infirmaries, day and night an early treatment was given each applicant and combined with personal advice and instruction against future exposure. Levity, indifference toward sexual irregularity, indecent stories, and undignified conduct were largely obliterated through maturity and responsibility of specially selected officers. Medical officers in command were required to make these stations centers of instruction, discussion, and statistical records in the prevention of venereal disease. Furthermore in cities without urological clinics or hospitals in which enlisted men stopped or through which they passed, proper medical facilities were provided chiefly through the United States Public Health Service. I have seen a number of letters from prominent citizens in such places admitting the importance of clinics and wards for these cases and regretting previous absence thereof. In large cities, like New York, approved clinics were frequently used as adjuvants of the military facilities. A most important preventive was restrictions on leaves of absence, so that longer than 24 hours was an exception, and departures from camp were timed early in the day. Cases of known exposure were marked as dangerous and specially observed at frequent short intervals. Diligent scrutiny of houses and women known to be sources of infection and against prostitution in general accordingly resulted. Civil authorities were stimulated to cooperate through a medical program corollary of the military program.

In camps medical care was provided for actually infected individuals, through special service in the cantonment hospitals. It was originally intended to send to Europe ten special venereal units, but this plan was abandoned and transferred to the United States, where special infirmaries were planned but given up when the armistice was signed. In the cantonment hospitals the venereal service had charge of these cases, usually commanded by an experienced urologist or by an officer well trained in these diseases.

One result of respect for these cases was seen by me in Camp Greenleaf, where many medical officers under instruction admitted that they had learned the importance of venereal disease to the individual and the community from what they had seen in camp in contradistinction to what they had failed to learn at home. No more important sociological teaching could be carried away by medical officers coming from small towns in which clinic and hospital facilities are either wanting or deliberately neglectful of venereal infection. These outcomes prove the efficiency of such instruction and the need of it especially along the lines of early correct diagnosis and of sane, safe, and consistent treatment. Orders were given to refer to and restrain in hospitals all acute venereal infection such as gonococcal and syphilitic. Expense to the Government in time lost and needless hospital expense was avoided by scrutiny concerning results in these cases.

Leaves of absence were refused the infected, syphilitics in particular. For study of the relations between these diseases and the community, especially syphilis, standard records and standardized treatment were laid down for physicians in command of troops. Such booklets secured conservative and avoided haphazard measures. What I have for at least twelve years insisted on in my own clinic and hospital practice was the rule, namely, cards of instruction for the patients themselves. Such cards add to knowledge, respect, and personal care of the several conditions. A valid part of the treatment is the laboratory which was adequate in the hospitals for discovery of gonococci, other bacteria, and *Treponemata pallida* in the dark field illuminator or smears. Weekly uranalysis for syphilitics under treatment was recommended, likewise frequent Wassermann tests. Thus what the civil clinics and hospitals of the highest order have learned, the military authorities adopted and practised with material benefit for all concerned—patients, medical officers, and the whole service in degree never seen in any other war or any other army of this war.

Brief note of the entertainment part of the campaign developed by the Commission on Training Camp Activities is worth while. It consisted of music, athletics, shows, education, club life, library service, hostess houses, and community service. These subjects have been previously mentioned from slightly different angles than the present.

Camp music was aimed to teach and train soldiers and sailors in songs of patriotism, inspiration, and good fellowship for the sake of stimulating high morale and unity. "It (music) not only spurs men on to greater courage and devotion in the hours of danger but makes them forget cold and mud and the weariness in long hikes." A booklet, "Songs of the Soldiers and Sailors," was published containnig sixty-nine popular patriotic and people's songs. Larger books, one each for Army, Navy, and Marines, were published by the Commission. Athletics in the Army and Navy were largely of the team and personal contest variety and stimulated rivalry, friendship, and fellowship. The aim has been athletic training of officers so that they will be able to direct military and recreative athletic work, and standardize instruction in physical training, tests, and sports.

In the twenty-nine Liberty theatres erected in camps, holding from 2,500 to 3,000 persons, wholesome, inspiring and recreative entertainment was given in approved plays and vaudeville. The ticket system known as "Smileage" made these theatres largely self-supporting and the cost without burden to the men. Even inside talent within the military organizations themselves were developed, as exemplified by "Yip Yip Yaphank." This work was

under a National Board of Review. Amateurs from adjoining towns frequently appeared in the auditoriums of the Y. M. C. A. and other bodies on Sunday afternoons and on evenings through the week.

Of great importance were boxing and wrestling because correlated with bayonet fighting and in the Navy swimming. Entertainment in shows was provided in theatres put up by the Government in camps and naval stations and in the auditoriums of the Y. M. C. A. and similar organizations. In the neighborhood of large cities theatrical managers, troops and artists volunteered for this work. Where these were lacking and otherwise in all camps the moving picture properly censored was of great value.

In educational work, aside from instruction concerning venereal disease, English was taught to illiterates and foreigners, supplemented by courses in civics, citizenship, the meaning and history of the present war, and the organization of American forces on land and sea. Improvement and promotion of individuals were aided by such courses as mathematics, report-writing, bookkeeping, stenography, typewriting, telegraphy (wire and wireless), telephony, engineering, navigation, warehousing, and management. There are also college-grade courses, such as memory-training, psychology, and other sciences; and lectures and informal talks on varied subjects.

Under this heading belongs club life exemplified by the Y. M. C. A., which in longer existence and experience is taken as example of the work of other organizations, namely, the Knights of Columbus, the Jewish Welfare Board, the Salvation Army. The Y. M. C. A. erected over 400 service buildings and a score of auditoriums in camps and naval stations, each having a recreation hall with stage, motion picture machine, piano, phonograph, library, games, and abundant letter-writing facilities. Three thousand secretaries were in the field doing general, religious, educational, building, and physical training work.

In some camps the Y. M. C. A. athletic and musical directors were very active. "Trench and Camp," a weekly eight-page newspaper, was published in thirty-five editions for army camps, and "Afloat and Ashore," a similar naval weekly, was also issued by the Y. M. C. A. The following record demonstrates the need of diversion and its far-reaching importance in indirectly preventing sexual temptation. At the Y building of a naval station in one month the attendance was 1,400,000. Over 30,000 attended 115 lectures and 16,000 were present in 850 educational classes; 82,000 appeared at 480 religious meetings, 130,000 at 330 entertainments, and 160,000 at 390 moving picture shows; money orders to the amount of $83,000 were sold and 650,000 pieces of mail were handled.

At Camp Greenleaf, in conversation with a secretary, I noted the difference between the policy of the Y. M. C. A. of to-day, particularly toward venereal disease, and the policy of thirty years ago or more when the strictly religious element predominated. This secretary replied: "Yes, if many of the members of that time could see us now they would think we were crazy."

(To be concluded)

Miscellany.

Assassination of Bossi.—The death of Pozzi at the hands of an insane male patient has hardly ceased to interest the attention of the average medical reader when the news arrives of the similar death at the hands of an assassin—this time a female—of L. M. Bossi, a contemporary gynecologist and obstetrician, best known for his method of mechanical dilatation of the cervix in the induction of premature labor. Pozzi, a Frenchman of Italian origin, was known chiefly through his operation of modified cesarean section, but was one of the leading physicians and statesmen of France. Bossi, a much younger man, was precocious as a gynecologist and a few years after graduation at Turin (1885) was in charge of the obstetrical department at Genoa and Novara. As chief obstetrician at the former University he at once sprang into prominence and the use of his mechanical dilators was but one of a number of innovations inaugurated by him. His career was marked throughout by a combative spirit and love of controversy. One favorite theme was the relation between utero-ovarian disease and the psyche, a bent which may have been indirectly responsible for his death. A woman obsessed in some way, a psychopathic patient who had been interned and whom he had sought to free, was responsible for his assassination while he was engaged in the preparation of an important paper. The mode of death is not stated. The deceased was also especially interested in abortion and in combating neomalthusianism.

Johannes Kupferscmid, an old Swiss Practitioner.—Rütimeyer, a practitioner in Basle, has reproduced a volume by an old local predecesssor which is regarded as an historical find. The original Kupferscmid was born in 1691 and died in 1750. At some time in his career—the date mentioned is 1715 but this may be an error—he published a work which fairly summed up the medical and surgical activities of his time and place. He taught that nature cures, that we must have clean surgery (with ligation of blood-vessels and suture to secure healing), that the wound dressings must be antiseptic and that wounds should heal without suppuration. As a military surgeon he had charge of over 17,000 soldiers from Berne and of these, during some campaign not mentioned, 400 were killed and 600 wounded. While his textbook was meant to cover medicine and surgery in general, military surgery was clearly his long suit, including war pestilences. The volume shows plainly that the writer was inspired with the highest medical ideals. On the one hand he robbed graves for anatomical material, which could not have come to him by legal means, in order to understand the structure of the body he was to treat; and on the other hand he established out of his own pocket a hospital for the public and "went broke" as the result of his philanthropy. He shifted about with no fixed abode until death overtook him in a strange land in needy circumstances. The reviewer, Dr. Seitz, states that the book should be read by beginners in medicine, for the prob lems of the practitioner remain but little change through the ages.

MEDICAL RECORD.

ACUTE PERFORATIONS OF ABDOMINAL VISCERA.

ACUTE perforations of abdominal viscera occasionally occur "out of a clear sky", so to speak, but generally follow conditions which should have suggested, if they did not give unmistakable evidence of, their presence. The appendix is, of course, the most frequent site of acute perforation; but we also have to deal with acute perforations of the stomach, gall-bladder, pancreas, duodenum and, more rarely, other portions of the intestinal tract.

In discussing this subject, William J. Mayo (*Surgery, Gynecology and Obstetrics*, January, 1919) credits the late Reginald Fitz, of Boston, with furnishing our earliest organized knowledge of the relation of appendicitis to general septic peritonitis. His work was done largely postmortem and his investigations connected cause with effect; but as they "began in the dead and ended in the grave" an exaggerated notion of the fatality of acute perforations in general was obtained. As the surgeon gradually developed a living pathology, the ravages of the fatal septic peritonitis were separated from the cause, and it was seen that not all perforations ended fatally.

Acute perforations of the abdominal viscera, so far as the peritoneum is concerned, are divided by Mayo into three stages: "(1) The stage of contamination, shown by more or less shock and localized pain and tenderness. This is followed by (2) the stage of reaction, we might well say the fatal stage of reaction, because so many patients with acute perforations slip by the stage of contamination in which they could have been safely operated on into (3) the stage of general peritonitis." He further says: "The apparent improvement which takes place in the period of reaction leads to the belief that the patient is better. Muscular rigidity and tenderness are usually present but may be absent in the middle-aged fleshy man whose peritoneum has become anesthetic by reason of fat deposited behind it."

Attention is called to the curious relationship between acute perforations of the gall-bladder and acute perforative appendicitis. The author has noted several instances in which there were simultaneous perforations of these organs. In these cases he has found that the gall-bladder usually contained stones, the pus had a strong colon odor, and its bacterial flora was similar to that in the pus escaping from the appendix; from which he thinks it would appear that in such cases the infection started in the appendix and was carried through the portal circulation to an already infected gall-bladder containing stones. He holds that perforations of the gall-bladder into the free peritoneal cavity should give the best results of any (because the anatomical surroundings of the gall-bladder are excellent from the standpoint of protection) were it not for the fact that the patient has usually had previous attacks of cholecystitis and believes the present attack similar to those that he has had before; hence early operations are not so likely to be insisted upon and the patient dies, not because of the acuteness or character of the infection, but because of the lateness with which the operative procedure is carried out.

Mayo finds that the danger of the acute processes of the pancreas, which may be spoken of pictorially as acute perforations, depends almost entirely on whether or not infection coexists. Radical treatment of these acute lesions of the pancreas has been advised and carried out by various authors in recent years; but the writer has been led to take a conservative view and to content himself with the anterior abdominal approach to the pancreas and drainage of collections, septic or otherwise, as they occur, rather than to anticipate their occurrence by pancreatic incisions.

Regarding duodenal perforations, it is stated that fortunately the duodenal content is more or less sterile, small in quantity, and has a tendency to gravitate to the region of the appendix; hence the preoperative diagnosis is often appendicitis. It is certainly true, as he says, that not infrequently the appendix is removed showing evidences of peritonitis on its surface but without disease of the mucosa, and the true cause of the trouble is not discovered. He even says that in nearly all of the earliest operations for acute perforations of the duodenum at the Mayo Clinic, a negative exploration of the appendix was first made and the perforation of the duodenum was found during further exploration. He calls attention to the fact that the duodenum is unusually well situated, anatomically, for the formation of protective adhesions to the gall-bladder, gastrohepatic omentum, transverse colon, etc., which quickly limit the spread of the contamination, and after some hours of pain from protective peritonitis there may be only muscular rigidity and localized pain to mark what was in the beginning a free perforation. The prognosis is good in cases of duodenal perforation if operation is done immediately, that is, within the first 6 to 12 hours. In a large unmber of cases operated upon at the Mayo Clinic within the first 8 or 10 hours recovery nearly always occurred. Regarding operation after this period has elapsed, the author says that the results were much less fortunate when the operations were done between 10 and 30 hours, for

a general spreading septic peritonitis quickly brings a patient to a condition in which an operation as a last resort will probably be unsuccessful; after 48 hours, however, he says a number will be greatly improved and operation can be done safely. In the early operation within the first ten hours not only will closure of the perforation avert a peritoneal infection, but a gastroenterostomy may be done, thus curing those conditions that depend on the ulcer.

Perforations of the stomach are more dangerous than those of the duodenum, since they are less favorably situated as regards protective agents and the stomach contents are more septic and in greater volume. A large amount of more or less septic material may escape into the area of the small intestine instead of gravitating down the right lumbar gutter. Anterior perforations of the stomach have a high mortality unless operated upon very early; but, as Mayo says, free perforations of the stomach are fortunately the least common of all perforations.

HELMINTHIASIS.

TAKING into consideration the fact that soldiers have been fighting in the near East where parasites of every kind abound and where conditions are extremely favorable for their spread, it was only to be expected that parasitic diseases should be very numerous among the troops there. In Egypt especially, where infection by *Schistosomum mansoni* is common, a considerable number of British soldiers were infected in this way. Dr. F. B. Lawton, writing in the *Journal of the Royal Army Medical Corps* for December, 1918, describes the early symptoms following infection by this worm. Twenty-four Australians who before enlistment had not traveled were admitted to the general hospital in Cairo in August and September, 1916, suffering from abdominal pain, enlarged and tender liver and spleen, fever, bronchitis, urticaria, and diarrhea. In every case there was also a striking eosinophilia and after prolonged examination eggs of *Schistosomum mansoni* were found in the feces. The incubation period was difficult to determine accurately, but the shortest period apparently was four weeks and the longest about three months. A notable and invariable symptom was urticaria present at some stage of the disease. Large wheals were distributed over the body and limbs, disappearing in from twelve to forty-eight hours in some cases, in others persisting for seven or eight days. The red cells were apparently unaffected, but the eosinophiles were greatly increased, never getting below 36 per cent., and usually about 50 per cent. When the earlier symptoms of the disease were severe and the pyrexial period protracted, considerable emaciation and weakness followed. Though resembling in a general way the early symptoms recorded for *Schistosomum japonicum* infection the illness in these cases was less severe. There was no ascites nor edema of the legs and no case terminated fatally.

The treatment of this condition is by no means easy. Those anthelmintics which are toxic enough to destroy the worms with certainty, are also dangerous. Torald Soliman, writing in the *Journal of Pharmacology and Experimental Therapy* for October, 1918, points out that the earthworms furnish with certain limitations valuable data on the toxicity of various anthelmintics. A substance not toxic to earthworms need not be considered of value for anthelminitic purposes. Soliman's general conclusions are: (1) The high toxicity of mustard oil explains the anthelmintic value of the closely related onion and garlic. (2) The high toxicity of copper sulphate suggests its use in enemas against oxyuris. (3) The anthelmintics that are most efficient chemically also stand high in their toxicity for earthworms. (5) Those practically nontoxic are not used as anthelmintics clinically. It must however, be borne in mind that the method, while of value in determining relative toxicity of a given substance, cannot be used to compare the clinical value of different anthelmintics, since this often involves factors other than the simple vermicidal efficiency, such as absorption, local and general toxicity, etc. Thus the highest vermicidal efficiency is possessed by mercuric chloride, cupric sulphate, and mustard oil, which substances are not available for the purpose, exemplifying what was said above, that those anthelmintics which are most vermicidal are too toxic to be employed as therapeutic agents.

Aspidium, chenopodium, pelletierine, thymol, betanaphthol, and chloroform, are highly effective; so is santonin in the presence of an appropriate solvent.

CHRONIC TORSION OF THE PEDICLE IN MOVABLE SPLEEN.

THE most frequent complication in cases of chronic torsion of the pedicle of a movable spleen is hemorrhage, which almost always occurs and is usually intracapsular, and this in turn gives rise to infarcts. However, in some instances the clots have been found on the surface of the spleen, this being due to the fact that the arteries have remained patent while the veins have become occluded. An increase of tension within the spleen is the natural outcome and this may lead to rupture of the capsule. The symptoms of intrasplenic hemorrhage offer nothing in particular which might lead to a diagnosis. As the amount of blood lost is usually small, especially in chronic cases, the general phenomena arising therefrom are few. In other words, the intensity of the hemorrhage is not enough to compromise life or even to indicate operative interference, because it is generally overlooked. The action of the hemorrhage is rather more a mechanical one, being the agent of splenicnecrobiosis and secondarily the starting point of infection.

Another complication is gangrene of the spleen, either partial or total and usually of the moist variety. As an example of this complication, Gersung's case is interesting, in which at autopsy large

and small perivenous necrotic foci were found, the arteries having remained patent. The gangrene will remain symptomatically latent up to the time of the occurrence of splenic suppuration, a process usually resulting from bacterial invasion coming from the intestine. The development of suppuration will be ushered in by a chill, rise in temperature and rapid infection of the peritoneum with suppurative peritonitis and death within a short time.

The type of temperature in splenic suppuration is the so-called hectic, with great oscillations, with a maximum during the day. In one case recorded by Coomans and de Cnaep, intestinal strangulation occurred, the symptomatology being that of occlusion, and it was only at operation that the torsion of the splenic pedicle was discovered.

Only in very exceptional cases has chronic torsion of the splenic pedicle any tendency to spontaneous cure, and if operation be not resorted to death will be the inevitable outcome, usually from peritonitis, rarely from splenic hemorrhage or rupture of the capsule. For the older surgeons this meant a very bad prognosis, but today, with bolder surgery and improved means of diagnosis, the prognosis is unquestionably improved.

The operative results, when the interference is resorted to in time, are clearly excellent, and splenectomy *per se* should give a mortality not higher than 3 per cent. at the present time. It naturally follows that if a suppurative process in the spleen is not dealt with surgically at the very onset, the outlook is far from favorable. But in chronic torsion of the pedicle, the spleen has been progressively put out of functional commission and at the time splenectomy is done, its part has been taken over by the lymph-nodes. Therefore, splenectomy should be resorted to just as soon as the temperature and general phenomena indicate the début of peritoneal infection, the cause of which will, in all probability, not be surmised until the abdomen is opened.

Priority in the Use of Carbonic Acid Snow as a Caustic.

During the war the European medical journals depended largely for non-military matter on their American exchanges. Now that hostilities are over and the *status quo ante* is reappearing it has seemed to us that the same journals are going to the other extreme of ignoring American medicine. This course may be in part justifiable, and it is, of course, quite likely that the military men who have returned to civil practice are unaware of what has been done in certain fields on this side of the water. We refer especially to an original paper by Lortat-Jacob and Vitry in *Le Progrès Médical* for May 31. The subject is the carbon dioxide snow caustic apparatus and allied methods of using cold. The study of this resource by the authors dates back before the war. Various forms of apparatus and modifications of technique appear to be in use in Paris. The author uses an apparatus devised by Beclerc in 1913. Two figures are given, of which one shows the charging of the so-called cryocautery with the acid while the other illustrates the commingling of acetone with the acid. There is not necessity to give the full technique and uses because this method originated with Pusey, an American, in 1906, and as a rule all foreign articles on the use of the resource give full credit to the Americans, and mention it as a distinctly American resource. It is, of course, possible that Bordas and Beclerc made an independent discovery during the period 1912-13 when they reported the "cryocautery" to the Academy of Science and Academy of Medicine respectively; but it is not easy to understand how they could have overlooked Pusey's priority. Neither the latter nor any other American is mentioned.

Whales and the Echinococcus Disease.

Van Deinse discusses in the *Nederlansch Tijdschrift voor Geneeskunde* for May 17 the subject of how the echinococcus disease reached Holland. The question is, of course, of general interest as a problem in geographical pathology. The part played by the dog in the transmission of this affection is well known, but how did the dog first contract the malady? How also did the disease spread to various quarters of the world as a new malady? It is said that this affection is endemic in Iceland and that it eventually reached Friesland from that locality. Not only Friesland was attacked in the eighteenth century, but many other seaports along the North Sea and English Channel. The connecting link appeared to be the whale fisheries, originally a Basque industry, with headquarters at Bordeaux. In the seventeenth century the Channel ports and later the North Sea ports engaged in the whale-catching industry. Friesland, possibly infected from Iceland, also engaged in whaling, appeared to be a distributing point of the infection. Not only whales, but also seals and other Arctic fauna, were perhaps infested with echinococcus disease, which was conveyed directly to mankind when in starving seasons they ate this flesh and to dogs and cats in the same manner, the animals then serving as hosts for the parasite along with mankind. In time this maritime industry went out of use. Recollections of old whalers, however, testify to the custom of taking dogs along on whale ships, so that dogs could become infected aboard ship and menace the home dwellers.

News of the Week.

Against Fraternizing with Teuton Scientists.—The following resolution was passed at the annual meeting of the American Surgical Association, held in Atlantic City, June 16-18: "The representatives of the Scientific Academies of the Nations at War with the Central Powers, assembled to consider future international cooperation in science, deem it impossible to resume personal relations with the members of the scientific bodies of those powers until such bodies shall be truly representative of a national spirit that renounces the political methods and the forms of warfare which have violated previously accepted conventions and ideals, and have shocked and outraged the civilized world." The association also voted unanimously to drop all German and Austrian honorary fellows from its roll of membership.

A Franco-American Medical Entente.—An Associated Press report from Paris says that an organization has been formed there with the object of establishing permanent relations between American and French physicians and surgeons. Several commissions have been appointed by the organization. One of these will have in charge the establishment of a course of teaching for American physicians visiting France and another the founding of a bureau of information. A third commission will examine into means of organizing an exchange of articles on medical and surgical subjects between the journals of the United States and France.

Medical Corps and Red Cross Score Record.—A bulletin recently issued by the American Red Cross sets forth some of its work during the war, and characterizes the work of the medical department as one of the greatest accomplishments in the records of medicine. The medical department kept effective 93¾ per cent of the army. Of 195,000 wounded Americans, 182,000 have recovered. Statistics show beyond dispute that the American Army was the healthiest and cleanest army that ever fought. The greatest toll of deaths from disease was taken by pneumonia and influenza, the loss attributed to these diseases being 8,000. There were only 1,000 cases of typhoid fever in the army, 50 of which were fatal. Venereal cases never exceeded 4 per cent., an exceedingly low rate for an army in the field.

Work of Red Cross for Troops in France.—The report of the Bureau of Hospital Administration, prepared for the War Department, shows that during the conflict the Red Cross furnished more than 1,110,000 days of hospital care for American soldiers, admitting to its hospitals a total of 89,539, 37,000 being admitted during the last month of the war. When hostilities ceased the Red Cross was operating 22 hospitals, with 14,326 beds occupied. The Red Cross undertook the manufacture of all splints and the nitrous oxide gas used for anesthesia, the construction of emergency hospitals, the supervision of diet kitchens, and the operation of thirteen dispensaries, eight infirmaries, and eleven convalescent homes throughout France. In addition, the Red Cross extended assistance of many kinds to 2,800 French hospitals. In the last nine months of 1918 the American Red Cross delivered 21,988,060 surgical dressings, compresses, packings, paddings, absorbent pads and bandages, 177,726 drains, 1,463,200 splints and accessories. In addition to these there were many miscellaneous supplies furnished, among these being 10 laboratory outfits, 48 sterilizers, *x*-ray, dental, and electrical outfits. The report cites instances of the expedition with which supplies were rushed to the front in cases of emergency, as during the battle of Chateau Thierry, when within eight hours an order for 3,000 blankets, several thousand pillows, pajamas, surgical instruments, medicines, and supplies was filled and and the articles were delivered at the battle front.

Effort to Maintain Fordham Medical College.—An effort is now being made to raise $1,000,000 with which to continue the Fordham Medical School. A canvass to raise this sum has been started, and will be continued until August 1.

Regulations of the New York State Department of Narcotic Drug Control.—Commissioner Walter R. Herrick has promulgated the following rules and regulations for the administration of the Department of Narcotic Drug Control of the State of New York:

For the purposes of this department the term "drug addict" is defined as follows: Any person who has needed or demanded the administering, prescribing for, or dispensing of cocaine, opium, or their derivatives at more or less regular intervals for thirty consecutive days prior to the time such person applies to a physician, or a physician of any institution, for the administering, prescribing for or dispensing of any such drugs or their derivatives; provided, however, that upon the filing of the report of the case by the attending physician, or the physician of an institution in charge of the patient, with this department, it may rule that such person shall or shall not be recorded.

A physician, or a physician of any institution, before beginning the treatment of a person for drug addiction must make a thorough physical examination of such person and such other examination as is necessary to satisfy him that the patient is addicted to the use of cocaine, opium or their derivatives. *The physician, or the physician of the institution, must keep on file a statement of his examination with the name of the patient, his address, and the date of the examination.*

A physician, or physician of any institution, except in the City of New York, prescribing for, administering, or dispensing cocaine, opium, or their derivatives daily for more than thirty days to a patient shall register with this department, or its authorized agent, the name of such person, together with a statement of the physical or mental condition of such person and a prognosis as to the probable future necessity for continuing the prescribing, administering, or dispensing of cocaine, opium, or their derivatives to such patient; such prognosis shall include an estimate as to the length of time which, according to the judgment of the registered physician, or the physician of any institution, will be required to remove the necessity of administering the aforesaid narcotic drugs to such patient.

A physician, or physician of any institution, is expected to cooperate with the department of Narcotic Drug Control and is required to register, within forty-eight hours, with said department, the name, address, physical and mental condition and any necessary circumstantial information regarding any person who applies for professional treatment and whom the physician, or the physician of any institution, thinks is an addict.

A physician, or physician of any institution, issuing a prescription for or dispensing cocaine, opium, or their derivatives to an habitual user in any quantity whatsoever shall only do so upon the official triplicate prescription blank or official duplicate dispensing blank or official duplicate dispensing blank.

The first paragraph of subdivision 5 of section 427, Article XXII, Chapter 639, of the Public Health law reading: "A physician may, in the course of the legitimate practice, in good faith, of his profession, and for the purpose of relieving or preventing pain or suffering on the part of a patient, or to effect a cure, administer, prescribe or dispense cocaine or opium or its derivatives as follows:" shall be interpreted to mean that where a physician, or a physician of an institution, prescribes for, administers or dispenses opium, cocaine, or any of their derivatives to an habitual user thereof, such prescribing for, dispensing, or administering, not being issued in the course of professional treatment in the attempted cure of the addiction, or for relief in the treatment of any other disease or surgical operation, but being used for the purpose of providing the addict with the aforesaid drug or drugs sufficient to keep him comfortable, will be considered by the department as a perversion of the meaning of the words "good faith" contained in said subdivision.

While opium, cocaine, or their derivatives may legitimately be used in connection with or as part of the treatment for the cure of addiction, the prescribing for, administering, or dispensing of such drugs to an addict for self-administration by such patient shall not be deemed to constitute in itself legitimate medical treat-

ment for the cure of such addiction, unless the physician purposes either by a gradual reduction in the dose or by some other method of treatment to effect within a reasonable limit of time a cure of the addict.

No person shall sell at retail or furnish to any other person other than a duly licensed physician, dentist, or veterinarian, nurse attendant, or interne of any institution an instrument commonly known as a hypodermic syringe or an instrument commonly known as a hypodermic needle, except upon the written order of a physician. Every person who disposes of or sells at retail or gives away to any person either of the above instruments upon the written order of a physician, shall, before delivering the same, enter in a book kept for that purpose the date of the sale, the name and address of the purchaser, and a description of the instrument sold, disposed of, furnished, or given away.

The commissioner also announces that the physicians of the State must register at once, under pain of revocation of their license to practise medicine or of being prosecuted as law breakers.

Registering of Drug Addicts.—Beginning with July 7, it became necessary for every drug addict to register with the State Department of Narcotic Drug Control at 128 Prince Street, and to obtain a dosage card before it is possible for him to have any drug prescribed for him. This card bears the name, address, and description of the addict, and certain information with reference to his occupation and employer. Drug addicts will be known by number, the card being numbered by the agent of the department and signed by the applicant. The details of the system are set forth in the new rules, above given, for the control of drug addiction, just issued by the Department of Narcotic Drug Control. Physicians are obliged, where an incorrect dosage card is presented, to keep it, report the holder, and return the card to the department office.

Government Regulates Dispensing of Alcoholic Drinks by Physicians and Druggists.—The Internal Revenue Bureau of the Treasury Department has issued new regulations governing the dispensing of alcoholic drinks by drug stores and physicians for medicinal purposes. Physicians may prescribe wines and liquors for internal use, or alcohol for external use, but in every such case each prescription shall be in duplicate, and both copies must be signed in the physician's handwriting. The quantity prescribed for a single patient at one time shall not exceed one quart, and in no case shall a physician prescribe alcoholic liquors unless the patient is under his constant personal supervision. All prescriptions must indicate clearly the name and address of the patient, including the street and apartment number, if any, the date when written, the condition for which it is prescribed, and the name of the pharmacist to whom the prescription is to be sent to be filled. Similar detailed restrictions on the sale of alcohol by drug stores have been provided. All prescriptions must be preserved, and each month the names of patients and the total quantities dispensed to each during the month must be transmitted to the collector of internal revenue. Pharmacists have been advised to refuse to fill prescriptions if they have reasons to believe that physicians are dispensing for other than strictly legitimate medicinal uses, or if patients are obtaining through several physicians quantities in excess of normal amounts.

Traffic Deaths Increase.—The National Highways Protective Society reports that for the first six months of this year 456 persons have been killed in New York State in traffic accidents, as against 369 during the same period of last year. During the month of June there were 50 deaths outside of the city of New York, against 49 for June, 1918. In New York City there was a decrease in the number of deaths from traffic accidents, there being only 45 killed, while in June, 1918, 57 persons lost their lives in this way.

Hospital for Rheims Incorporated.—The Supreme Court has approved the incorporation of the American Memorial Hospital which is to be erected at Rheims, France, through the efforts of the American Fund for French Wounded. A fund of $300,000 has been raised toward the first wing of the hospital, which is to cost $450,000.

Providence Physicians Raise Fees.—At a recent meeting of the Providence Medical Society it was unanimously voted to put a new schedule of fees into effect beginning with July 1. According to the new rates, office calls are $2; a visit to a patient's house during the day $3, a night call $5; for surgical cases, including confinement cases, a minimum charge of $25 is made; the minimum fee for major operations is $100.

Floating Hospital Opens Season.—The Floating Hospital operated between New York and the Seaside Home at New Dorp, Staten Island, made its first trip for the season on July 7. The hospital carries about 50,000 babies and their mothers during the months of July and August. This year a night service of 50 beds will be established, and continued regardless of the weather. The Seaside Home, which is greatly in need of a nurses' home, has been promised $50,000 for this purpose provided $150,000 can be raised.

Miss Alice Fitzgerald, formerly of New York and Boston, has been appointed chief nurse of the Red Cross forces overseas.

Dr. William J. French of Washington, D. C., has been awarded the Legion of Honor by the French Government in appreciation of his work in charge of the Children's Bureau, which he established in Paris as a war relief measure.

Dr. Joseph A. Blake of New York has received the Distinguished Service Medal for his services overseas during the war.

Dr. William E. Studdiford of New York has resigned the professorship of gynecology and obstetrics in the University and Bellevue Hospital Medical College to become the successor of the late Dr. Edwin Bradford Cragin, at the Sloane Hospital for Women.

Dr. Frederic C. Holden of Brooklyn has been appointed professor of gynecology and obstetrics at the University and Bellevue Hospital Medical College and head of the gynecological service at Bellevue Hospital.

Dr. Walter T. Dannreuther of New York has been appointed assistant professor of gynecology in the New York Post-Graduate Medical School and Hospital.

Colonel Richard P. Strong, M.C., U. S. Army, of Cambridge, Mass., has been appointed acting director of the Bureau of Hygiene and Public Health of the League of Red Cross Societies.

New York Village Needs Doctor.—The Chamber of Commerce of Moravia, N. Y., announces that there is an opening in that village for a wide-awake

physician. Full particulars may be had by writing to W. J. Cannon, secretary, Chamber of Commerce, Moravia, N. Y.

Vacancies for Physicians.—The Civil Service Commission of New York State announces the following examination to provide eligibles for the State service: Diagnostician and epidemiologist, State Department of Health, salary $3,500. Sanitary supervisor, State Department of Health, salary $3,000. Assistant bacteriologist, State Department of Health, open to women between the ages of 21 and 35; salary, $1,200 to $1,800; candidates should have a collegiate education or its equivalent. Surgeon, State Institute for the Study of Malignant Disease, Buffalo, open to men only, salary $2,000. Assistant physician, regular or homeopathic, to provide eligibles for the position of assistant physician in the State hospitals and for other positions of similar nature in various State and county institutions; salary, $1,200, with increase. Application forms must be obtained before July 21, and applications must be in the hands of the State Civil Service Commission, Albany, N. Y., by July 23, 1919.

United States Pharmacopœial Convention.—Dr. Harvey W. Wiley, president of the United States Pharmacopœial Convention, asks all competent and designated authorities to name and issue credentials to the fixed number of delegates to the tenth decennial convention to meet in Washington, D. C., on the second Tueday of May, 1920, at 10 o'clock, a. m., at a hall to be designated hereafter. The appointed delegates are requested to forward their credentials promptly to Dr. Noble P. Barnes, the Arlington Hotel, Washington, D. C., who will file them for consideration of the Committee on Credentials, which will be appointed by the President not later than March, 1920.

Rockefeller Foundation Reports on Malaria and Yellow Fever.—The second installment of the review of the work conducted by the Rockefeller Foundation during the year 1918 has just been made public. It deals chiefly with the work done in various sections of the United States with the object of eliminating malaria and with the campaign against yellow fever carried on in Guatemala and Ecuador. It tested the possibility of ridding a community of malaria by carrying out antimosquisto measures in four towns in Arkansas. Its purpose was to stimulate other communities to take similar measures at their own expense, and as evidence that it is well within the means of a community it was shown that the per capita cost was only 44 cents. The results as tested by the number of calls made by physicians on persons who were suffering from the disease were striking. In Hamburg, Ark., the number of calls fell from 2,312 in 1916 to 59 in 1918, a reduction for the period of 97.4 per cent. The report tells how the work was carried on with the cooperation of the United States Public Health Service and announces that during the coming year the movement will be extended in Mississippi to the whole of Sunflower County, which will bear one-half of the expense. The attack on the seed beds of yellow fever began with the appointment of Major General Gorgas as Director of the yellow fever work of the International Health Board with freedom to carry out the recommendations of the Yellow Fever Commission. Systematic attempts were to be made to destroy the disease at its sources. The report tells of the work of Dr. Joseph H. White in combating the epidemic of yellow fever in Guatemala during the first half of 1918, which was brought under control before Dr. White returned to this country in September, 1918. With the hearty cooperation of the Government of Ecuador and of the municipality of Guayaquil, measures for active yellow fever control were inaugurated November 27, 1918. The hope is expressed that the measurable results in the reduction of infection will be disclosed in the near future.

How Health Administration May be Improved.—The May issue of the New York State Department of Health Bulletin calls attention to the information furnished by the recently completed survey of health administration in the cities of New York State, which has served to bring to the attention of municipal authorities both the excellencies and the deficiencies of their health departments. Certain defects were found to be nearly universal. Among these is the inclusion under health department of plumbing inspection, garbage collection, and similar activities, which leads a community to believe that it is spending a dollar per capita for health when it is spending but a fraction of that amount for proper health functions. The balance goes to operating activities rightly belonging to the street or public works department. A second defect has been found in the lack of coordinated effort. Aside from the independent pursuit of the same or different goals by private and public organizations there was too often developed a maladjusted and wasteful expenditure of public funds. Another prominent defect, and one that has a marked influence in the efficiency of the health department, it is pointed out, is the lack of adequate records and the failure to make effective use of them when they do exist. "The man who does not keep his records wastes money or effort or both. To secure appropriations he should be able to show their need and the best way to do this is by showing the amount, character, and desirability of his work."

Physicians Increase Fees.—The Madison County Medical Society (Ala.) has revised the fee schedule of its members. It has raised all fees 50 per cent. House calls have been $2 and they will now be $3.

American Optical Glasses Made in Abundance.—Until recently most high grade material suitable for modern optical instruments has been made in Germany. As a result of the war American manufacturers have been stimulated to research in methods of manufacturing these supplies and have attained such a degree of success that America need no longer be dependent upon German factories to supply a flawless glass for scientific instruments. Those in a position to judge state that the home-made product is both plentiful and satisfactory.

The National Exposition of Chemical Industries announces that its fifth annual exhibition will be held in the First Regiment Armory and Coliseum, Chicago, during the week of September 22, 1919,

under the management of the International Exposition Co., whose headquarters are at 405 Lexington Avenue, New York City.

Obituary Notes.—Dr. NATHANIEL BOWDITCH POTTER died at his home in Santa Barbara, Cal., where he removed several years ago because of failing health, on July 4, aged 49 years. Dr. Potter was born in Keeseville, N. Y., graduated from Harvard Medical School in 1894, and practised medicine in New York City. He was formerly professor of clinical medicine at the College of Physicians and Surgeons; chief of the medical department of St. Mark's Hospital, consulting physician to the French, the New York Throat, Nose and Lung Hospitals, and to the Central Islip (L. I.) State Hospital. He was a member of the American Medical Association, the New York Academy of Medicine, the Harvard Medical Association, the American Climatological and Clinical Association. He was Officier de l'Instruction Publique and Membre Correspondent de la Société Medicale des Hôpitaux de Paris.

Dr. HENRY S. OPPENHEIMER, a well-known ophthalmologist, died at his home in New York City on July 5, aged 75 years. He was a graduate of the College of Physicians and Surgeons, in 1876, a member of the American Medical Association, the American Ophthalmological Society, the American Congress of Physicians and Surgeons, the New York Academy of Medicine, and ophthalmologist to the City Hospital and the Montefiore Home.

Dr. CAROL GOLDENTHAL, a graduate of the University of Vienna, in 1906, assistant surgeon to the Harlem and Bronx Dispensaries, died from the effects of blood poisoning at his home in New York City, on July 2, aged 38 years.

Dr. CLEMENT A. PENROSE of Baltimore died on July 4, in the Church Home and Infirmary in that city, from blood poisoning contracted in France. He was 45 years old, and a graduate of Johns Hopkins University in 1897. He served as major in the Medical Corps of the army, spending some time with the British and American armies studying sanitation in the camps at the front. Dr. Penrose was a member of the American Medical Association, Southern Medical Association, Johns Hopkins Medical Society, and a number of other organizations, both medical and lay.

Dr. HUGH FORBES MCGAUGHEY of Winona, Minn., died suddenly in Tacoma, Wash., on June 20, aged 45 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1896, and one of the best-known surgeons of southern Minnesota. He was local surgeon of the Northwestern and the Chicago, Burlington & Quincy railways. He was a member of the American Medical and the Minnesota State Medical Associations.

Dr. ANDREW V. CHERBONNIER, captain in the U. S. Army, retired, died at his home in Baltimore, on June 25, aged 93 years. Captain Cherbonnier entered the army at the outbreak of the Civil War, and, following the war, was stationed at a number of points in the West and Southwest.

Dr. FRANK M. DONOHUE of New Brunswick, N. J., a graduate of New York University Medical College, in 1881, died suddenly at his summer home at Cedar Crest, near Bound Brook, N. J., on June 30, aged 60 years. He was surgeon to St. Peter's Hospital, New Brunswick, N. J.

Correspondence.

RULES OF THE NARCOTIC DRUG COMMISSION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In all probability, there will soon be a realization by the medical profession and the public of the tremendous revolution in their affairs brought about by the rules just promulgated by the new Narcotic Drug Commission. Under one of the rulings, which has "all the force of statute law until otherwise rescinded or revoked," every one who in the course of sickness, injury, or infirmity, has to have morphine for a consecutive period of thirty days to relieve his suffering, or to assist in his cure, is adjudged a "drug addict." Such a one is to be reported to the Drug Commissioner with a full diagnosis and prognosis, mental and physical, in this case. In order to make this report compulsory, the law under which the commission was created abrogated for the purposes of the act all the privilege of secrecy hitherto existing between physician and patient. When it is remembered that the body with whom these hitherto inviolate professional secrets are to be lodged is entirely political, the change in the affairs of the hapless sick and dying may not only be called tremendous but appalling.

Let it be remembered also that in lingering and fatal illnesses of all kinds there is but one boon to the sufferer and to those who have to witness their suffering—the use of morphine. Without it the agony from incurable cancer could never be endured, and self-destruction would be an every-day occurrence. There is the best legal opinion that this violation of professional secrecy invalidates the act upon which this political and non-medical commission was created, yet neither medical men nor the organized medical bodies can afford to appear as opponents of the law of the land. They were told by the counsel of the Medical Society of the County of New York that opposition to this law on the part of more than three members combined could be construed as conspiracy by the State.

There is one form of opposition that cannot be denied even under a drug commissioner who can make and unmake laws regulating the practice of medicine in this way. This privilege is the right of petition. Already there is under way a project to get as many of the 15,000 physicians of the State as possible to petition the Legislature at the coming session to repeal the law under which the Commission for Narcotic Drug Control was created. In no other country in the world does it obtain that the lawmakers have found it either necessary or profitable to resort to a measure of this kind to control the illegal sale and use of narcotic drugs, which everywhere else are fully controlled under the law by the police acting in harmony with the medical and pharmaceutical professions, while leaving the sick and dying undisturbed and unexposed. To register and class these sufferers with the criminal and degraded users of drugs and to throw this odium around what in every case is the house of suffering, and in many cases soon to be that of death, is a disgrace to a civilized community.

JOHN P. DAVIN, M.D.

NEW YORK.

OUR LETTER FROM LONDON.

(From Our Own Correspondent.)

LONDON, June 12, 1919.

Demobilization of the Medical Profession.—The problems of demobilization will evidently take a long time for their solution. To the ordinary man, who merely wants a job done, it is exasperating to be told that there are no men to do it, when daily he hears of people who are out of work, and people who are in receipt of unemployment pay. To those whose businesses require big labor power, and to contractors who cannot tender for work, as their insecure position in respect of men makes it impossible for them to sign a time clause, the situation is a maddening one. For medical men the position is not without grave difficulty, for many are finding that the practices to which they intended to return have considerably dwindled during their period with the colors; if those who have not been actually under arms are benefiting the situation is not agreeable, but as a matter of fact these men in many instances could not be spared, however willing to go, and for over four years have worked double shift. There is probably ample opportunity for all medical men who desire it to get fairly soon into prosperous routine as general practitioners, but as a matter of fact a large number of the returned medical officers in navy and army do not want to go into general practice, whether they have ever lived the life or not. The enormous expense of housekeeping, and the difficulty of finding houses, coupled with the general social uncertainty have turned the eyes of most young men toward government employ, where the salaries are fixed and the chances of failure, save through gross default, practically nil. It is the feeling of social insecurity, rather than any minimizing of its scientific value or intense interest as a career, that is keeping many medical men, as they are demobilized, from going into general practice, while it is certain that in the near future a very large number of medical government posts must be created. In whatever pattern the Ministry of Health Bill reaches the Statute Book, and whatever the provisions of the Medical Services Bill, there will be required a large number of whole-time or part-time salaried medical officers; while the education office, the tuberculosis service, and the service for the prevention of venereal diseases are certain to call for many men.

In these circumstances it is not surprising that a shortage still prevails in the general medical service of the country, to the puzzledom of the public, who see in doctors yet another class which on the one hand seems short, and on the other a good deal unemployed. A large number of them at present unemployed, who have seen military service will shortly obtain whole-time or part-time employment under the Ministry of Pensions. At the present time there are 140 medical boards sitting, under the ministry, to consider the cases of the disabled sailors and soldiers. These boards account for upward of 3,000 medical men, while outside the boards over another 1,000 medical men are officially employed in the care of the disabled, giving whole-time or part-time service. The Minister of Pensions has informed all these medical men by circular that a large number of the demobilized medical officers are desirous of these posts, and, while every appointment now held will certainly come in for service, the probability is that the principle will be adopted of giving preference to those who have served in the navy or army. Instructions, indeed, have already been given that wherever possible those medical men, employed by the Ministry, who have not served with the navy or army, should be in readiness for replacement by those who have so served. Here there are numerous openings, but we cannot hope that the prospect of those who take the posts will be very good, for to do so would be to hope that the problem of our disabled would remain with us for a long time. On the contrary, we trust that in a short time all the necessary arrangements for restoring to useful citizenship as many of the married as possible will have been made, together with the machinery for continued courses of treatment; and when this position is reached, there cannot be room for the services of over 4,000 medical men in regular employ, however piteously large our list of crippled heroes is.

The Founding of a Bacteriological Chair in London.—It has long been a reproach to medical education in Great Britain that the scientific teachers, whose professional work is sure to be poorly rewarded, should also be ill-paid for their academic activities. The physician, surgeon, gynecologist, and clinical specialist attached to a hospital, and teaching in the associated medical school, may be able to disregard the amount of fees that he receives for his educational work—that work goes hand in hand with his official connection with the hospital, from which he derives, via the public, all his professional income. That income may be large or small, being dictated to some extent by his talents, and to a more important extent by public caprice; but large or small it is to private practice, led up to by his hospital connection, that he looks for his real income, the fees for teaching being not considered—and indeed they are always inconsiderable. The bacteriologist can look for no such public support, save in a few cases, and if his educational work is badly paid he cannot devote himself to science without a private income. And herein lies a danger for the public; when the possession of a private purse gives a man a predominant opportunity, we may be sure that now and again a better man has to go to the wall. Of late years this position has begun to be recognized, and some satisfactory endowments have been made of the purely scientific side of medicine. One such has recently been announced at the London Hospital, the largest hospital in the metropolis. At a recent meeting of the College Board of the Hospital, a letter was read from the Goldsmiths Company, the wealthiest livery company in the city, offering the college £15,000 for the endowment of a chair of bacteriology. This handsome donation is not only admirable for its purpose, but it may turn the minds of wealthy individuals and corporations in a like direction, and other of our medical schools may at last have the reproach lifted from them that they cannot pay their scientific teachers. The Goldsmiths Company in

making their gift to the London Hospital Medical School expressed the hope that their action might act as an incentive to others, and if this should turn out to be the case the public will enormously benefit. The movement to make London a great post-graduate center for European medicine is founded upon reasonable as well as laudable ambition, but there should run with it a movement for ensuring that the best teachers are attracted to the medical schools, in which way alone can we be certain that the post-graduate teaching will be of the highest standard. What is wanted is public sympathy; if the scientific needs of medicine were understood in England, as they are apparently in America, the necessary funds would soon be forthcoming. But science has little appeal for charitable persons in this country; money can be found for the treatment of the sick—not easily but still in creditable bulk, but none is forthcoming for the maintenance of that treatment on a high scientific level.

The Pay in the Indian Medical Service.—I referred last week to the lamentable fact that the year 1918-1919 saw a serious recurrence of plague in India, which has now groaned for twenty years under a heavy if fluctuating incidence of this disease. The fact brings home to us that we still have much, almost everything to learn of the etiology of plague—to say that it is spread by rats is only part of the story. It is becoming evident that atmospheric and barometric conditions play a great part in the severity and diffusibility of plague, and immediately we have laid open before us a vast vista of investigation. This should furnish the modern government with an additional argument for improving the conditions of employment in the Indian Medical Service. This service has undergone recent modifications for good, but it remains an ill-paid career, where work is heavy and holidays difficult to obtain. Now it is to the Indian Medical Service that it is natural to look for an organized effort to comprehend the origin and development of a disease that lays such a heavy toll on the manhood and prosperity of some of the fairest portions of the Empire. And from that service great results might be fairly expected in exactly the desired way if the terms offered were more generous. The officers in the Indian Medical Service have more to do and shorter vacations than ever, but their pay is only worth 60 per cent. or so of what it was at the beginning of the century, and if this injustice is not remedied the great medical schools will hardly continue to recommend their students to seek the Indian army as a career. Moreover, it is very extravagant of any government to save in preventive medicine.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, June 5, 1919

Red Cross.—The proposed League of Red Cross Societies, having for its purpose the association of the Red Cross Societies of the world to fight the misery produced by disease and calamity, has now been organized on a definite basis, with its headquarters to be situated at Geneva. The Board of Governors, which will hold office until a general council is convened, consisting of members of Allied Red Cross Societies, has just held its first meeting in Paris. The Board consists of Mr. Henry P. Davison (America), who was elected chairman; Sir Arthur Stanley (England), Comte Kergorlay (France), Count Frascara (Italy), and Professor Ninagawa (Japan).

The objects of the Red Cross League are: (1) To encourage in all countries a Red Cross organization, having as purposes the improvement of health, prevention of disease, and mitigation of suffering, and to secure the cooperation of such organizations for these purposes. (2) To promote the welfare of mankind by furnishing a medium for bringing within the reach of all peoples the benefits of science and medical knowledge. (3) To cooperate in relief work in case of disasters.

The League is the outgrowth of plans which have been developed by the Committee of Red Cross Societies during the past five months and by a conference of some of the leading medical experts of the world held at Cannes in the early part of April. The five Allied societies which have founded it will invite other societies to become members. The control of the League will be by a general council composed of representatives from all societies which are members, meeting at stated periods. In the intervals between these meetings, the control of the League will be exercised by a governing board of fifteen members elected by the general council and two ex-officio members. The Board of Governors has authorized immediate steps for carrying out the purposes of the League. It selected Geneva, the home of the International Red Cross, as its headquarters.

The League has not had to wait long for occasion to test to the fullest degree its working ability. With the purpose of devising a plan to combat the epidemic of typhus which has reached serious proportions in Southern and Eastern Europe, the Supreme Economic Council has appointed a committee to confer with representatives of the Red Cross to prepare a definite scheme for submission to the respective Governments. The Director General of the League has been in conference with the Supreme Economic Council regarding the situation and the necessity for immediate action on a large scale. Reports from Poland and from other parts of Eastern and Southern Europe picture the suffering there as beyond imagination. Thousands are dying for lack of medical care and there is a serious scarcity of all medical necessaries. The menace to the rest of the world is fully appreciated by the Supreme Economic Council, which has received reports from various sources regarding the rapid spread of typhus and the necessity for taking immediate action. Added to the menace of typhus is the danger of an epidemic of cholera in Europe and the Red Cross League will be consulted in regard to this feature of its program.

The Supreme Economic Council has decided to ask the League of Red Cross Societies to extend to Northern Russia the measures recently considered for supplying medical aid to the countries of Southeastern Europe.

The death is reported of Dr. Edvard Berg, director of the Institut Suédois de Kinésithé-

rapie of Paris, and of the section of Mécanothérapie at Evian-les-Bains. Dr. Berg had been in poor health for more than a year, his vitality having been undermined by his incessant work during the war at the military hospital in the Grand Palais, where the kinesitherapy department, which he founded, organized, and supervised continually in every detail, has rendered services of inestimable value in the reeducation of hundreds of maimed and disabled soldiers. He died at Lausanne after a serious operation. Dr. Berg was 49 years of age. He was one of the leading and most highly esteemed members of the Swedish colony in Paris. Many of the mechanical instruments he invented have been adopted by the French Ministry of War for application in the schools established throughout France for teaching of trades to soldiers crippled in the war, Dr. Berg having waived all patent rights as regards his inventions.

6. Functional Aphonia. Paul V. Winslow.

6. Functional Aphonia.—Paul V. Winslow draws attention to the following facts: The speech mechanism is a complex organism composed of the air tract, vibrating cords, resonating chambers, muscles, mucous membrane, nerves, tongue, teeth, hard and soft palate, anterior and posterior pillars, and the lips. The larynx which contains the vocal cords, is the most important part of the speech mechanism and respiration and phonation are its chief functions. Respiration is under the control of a nerve center in the brain and is an automatic act which can be modified but not suppressed by voluntary effort. Phonation is also governed by a center in the brain and is under the control of the will, except during the reflex actions of sighing, laughing, coughing, and cries of fright. The larynx is a triangular box composed of cartilages lined with mucous membrane and held together by muscles. With this box and attached to the cartilages are the two vocal cords, whose movements are controlled by the adductor and abductor muscles. In singing and speaking the adductor muscles bring the cords close together, whereas the abductor muscles carry the cords away from each other as in inspiration. The position of the cords varies; during phonation they are close together, during quiet respiration they are midway between phonation and deep inspiration, and in deep inspiration they are abducted as widely as possible. In the cadaveric position the cords are between that of quiet respiration and phonation. The author then points out that any lesion or disease in the body paralysis of the abductor muscles is organic; on the other hand, when the adductor muscles are primarily affected, the paralysis is functional and not organic. It is therefore comparatively easy to distinguish between an organic and a functional aphonia. In the functional loss of voice, hysteria is the principal cause and occurs chiefly in young women, sometimes in girls as young as eight years General weakness, anemia, neuropathic disposition, and inflammation of the larynx are predisposing factors. Any sudden emotion, fright, mental or physical shock, exposure to incessant gun fire and gruesome sights, great joy or grief, are all important causes of this condition, which is naturally more likely to develop in neurotic individuals. In hysterical mutism, the patient cannot even whisper, the condition being one of aggravated functional aphonia combined with paralysis of the whole speech mechanism. In hysterical cases, the onset is usually sudden and speech is reduced to a whisper; in cases due to general or local weakness, the onset is more gradual. Winslow draws attention to the necessity of a thorough examination of the larynx in such cases, as the condition is frequently diagnosed as acute laryngitis and if it persists it is often called chronic laryngitis. He cites a number of cases which have come under his observation and outlines his method of treatment, which is as follows: The patient is seated before the observer and a careful history of the case is taken. A careful examination is then made of the larynx with the laryngeal mirror and the movements of the vocal cords and condition of the mucous membrane from the larynx down as far as can be seen are noted. If the case is one of functional aphonia, the mirror is removed and the patient is asked to take ten or twelve deep breaths, and then to raise the arms above the head ten or twelve times. Then, looking the patient directly in the eye, the observer tells him there is a little piece of cartilage in his throat which is slightly out of position and as soon as the observer puts his finger down his throat and fixes it, he will be able to speak. Then standing to right of patient with his left arm around patient's neck, the index finger of left hand pushing in the cheek between upper and lower jaw to prevent patient from biting, the observer pushes index finger of right hand down throat of patient beyond the epiglottis and holds it there until patient makes an attempt to get away. He continues to hold finger there until it begins to get uncomfortable, when the patient will, as a rule, make a sound like a grunt. Observer then takes his finger away and begins to count from one to five, urging patient to count with him. If this does not work, he repeats the count much louder than before, and it may be necessary to yell before the patient begins to use his voice. When the voice is restored, the author states that he keeps it working for some time so that the patient will become accustomed to it. He adds that the attitude of the operator must be firm but gentle and he must inspire the patient with confidence in his power to restore the voice.

7. The Autotoxic Factor in Sympathetic Ophthalmia.—Arnold Knapp reports four cases in which an injury or an operation causing iridocyclitis in one eye was followed by serous iridocyclitis in the second eye. In the first case, the symptoms were mild and yielded readily to treatment. In the other three the ocular symptoms were those typical of serious cyclitis, namely, moderate ciliary congestion, readily dilatable pupil, posterior corneal deposits, vitreous opacities, associated with fundus changes which have been described under the name of chorioretinitis sympathica, neuroretinitis, ad macular changes. The characteristic small choroidal spots appeared without any pigmentation in the periphery of the eyeground after the process had existed for about six weeks, and some of them later disappeared without leaving any trace. In the two more severe cases there were larger irregular chorioretinal foci. Neuroretinitis was present in all. The macular chages consisted in irregular choroidal pigmentation, appearing later in the course of the disease and apparently not affecting vision. Anatomic examination could be made in only two of the three cases in which an enucleation was done. The

changes in the eye in Case I consisted in mononuclear lymphocytic infiltration of the uvea, particularly of the iris and ciliary body, and slight optic neuritis. In Case II, the evidences of a purulent inflammation preponderated in the iris and ciliary body, but the typical sympathetic infiltration was pronounced in the choroid, especially in its posterior half about the inflamed optic nerve. In the case in which enucleation was not done, the injured eye is now white; there is secondary cataract, with posterior synechia; light projection and tension are normal. In these cases the autotoxic factor depended upon the following: There was generally a history of improper diet and overeating, often associated with constipation. Examination of stools gave a highly toxic, acid stool in two cases, with large excess of skatol and indol and exclusively Gram-positive bacteria. Treatment by mercurial inunctions, sodium salicylate, and pilocarpine sweats had little effect. Nor did elimination of associated infections, such as abscessed teeth and nasal sinus empyema, exert any influence on the course of the disease. Diet regulation, thorough catharsis and colon irrigations were the most effective agents. The author states that though he realizes the temerity of advocating autotoxemia at the present day and is fully conscious of the many imperfections in the presentation of these four cases from an autotoxic standpoint, he feels the importance of investigating for a toxic factor in sympathetic ophthalmia. Though objection has been made to Elschnig's hypothesis, if such a factor is found to be present its elimination in a prophylactic endeavor, as Elschnig suggests, cannot be passed by.

1. The Croonian Lectures on the Rôle of the Sympathetic Nervous System in Disease. Lecture IV.—W. Langdon Brown in this fourth lecture considers the relation of diabetes insipidus and circulatory diseases to the sympathetic. He points out that several different conditions, which he considers under the four following heads, have been described as diabetes insipidus. (1) Syphilitic meningitis. This condition at the base of the brain is responsible for a large proportion of cases, and is a frequent cause of diabetes insipidus in children. The fact that the nearer the meningitis is to the interpeduncular space the more apt it is to excite diabetes insipidus, suggests irritation of the pituitary as the mechanism of production. (2) Disease of the pituitary body. Experiments would seem to show that just as the pars intermedia contains a substance exciting glycosuria, the posterior lobe contains something capable of exciting diuresis, and that this might be brought into action by manipulation or transplantation of the posterior lobe, injection of its extract, or by stimulation of the sympathetic nerve supply. (3) Primary defect in the kidneys. This type was described by Myer in 1905. In such cases, the patient is incapable of secreting urine of normal concentration, so that he requires a much greater quantity of water to remove the normal products of metabolism. The condition resembles interstitial nephritis, and should observations on the blood pressure show that it is distinctly raised, an additional point of resemblance will be provided. In this type of diabetes insipidus restriction of ingested fluids is a futile and cruel procedure, for the patient must excrete a dilute fluid, and if fluid is not given to him he must obtain it from his own tissues. Brown states that he is not satisfied that this type is entirely distinct from the pituitary type; he looks upon it as essentially a form of chronic interstitial nephritis and urges that it be not classed as diabetes insipidus. (4) Type resulting from polydipsia. In this type there is no evidence of syphilitic meningitis, pituitary disease, or renal incapacity, the polyuria being generally regarded as secondary to polydipsia. The free administration of valerian is of benefit in such cases, as in the syphilitic type when combined with antisyphilitic treatment. Brown believes that a structural or nervous irritation of the posterior lobe of the pituitary affords the most plausible explanation of diabetes insipidus and that this condition without local lesions may be ranked among the diseases due to the sympathetic. He then takes up the question of the vasomotor system in disease. The function of the vasomotor system is twofold, to regulate the general blood pressure and to regulate the local blood supply. At first sight it appears surprising that the organs composing the "tripod" of life—the brain, the lungs, and the heart—either lack or are very scantily supplied by vasomotor nerves. This is so, however, because these organs are so important that their needs cannot be subservient to the vasomotor, but must be protected at all costs, and this may cause them in disease to override the interests of the general economy for their own advantage. He first considers the brain and the vasomotor system, referring to Munro's dictum that the quantity of blood in the cranium is a constant and to the fact that the blood supply to the brain is mainly controlled by means of the splanchnic area which is controlled by the vasomotor center within the cranium. He points out that in order to avoid cerebral anemia the general blood pressure must be kept at a point above the intracranial pressure and shows that in cerebral hemorrhage if the blood pressure is reduced to the point at which hemorrhage is checked, there is danger of starving the medulla, the one part of the brain which must keep up its supply of arterial blood since it contains the centers which are essential to life. The necessity of maintaining the blood pressure at a higher level than the intracranial establishes a vicious circle, for the hemorrhage produces a rise of pressure, and the rise of pressure increases the hemorrhage. It may be asked, therefore, how a cerebral hemorrhage can ever be recovered from. The answer appears to be that the tentorium can shelter the medullary centers from some of the ill-effects of the high intracranial pressure and this idea is supported by the rapidly fatal effect of even small pontine hemorrhages, when no such shelter is possible. Intracranial tension may be diminished by lumbar puncture, which reduces blood pressure and, therefore, liability to hemorrhage. The fact that more than one hemorrhage into the brain substance is so frequently found may be explained as follows: the large hemorrhage drives up the general blood pressure so much that diseased arteries in other parts of the brain are unable to withstand the strain. The author then discusses the effect of absence of direct vasomotor effects in the pulmonary vessels and shows that in edema of the lungs the left heart is already loaded to its full capacity while the right heart still goes on beating, forcing blood into the lungs until they become engorged, since they are unable to shut off any of the blood supply by vasoconstriction. Turning his attention to the heart, the author shows how anything which leads to an unduty high pressure must use up the cardiac reserve, pointing out the tremendous amount of work that the heart is required to do—normally equivalent to lifting a ton of blood 122 feet high per day. As to the origin of hypertension, the belief that a rise of blood pressure can occur before structural muscular lesions take place, though not universally accepted, is in accord with what we know of the general vasomotor constrictor effect of sympathetic stimulation. Barger and Dale have shown that bodies resulting from putrefactive decomposition of proteins, which have a pressor effect, may explain how dietetic factors may produce hypertension, and in his

second lecture the author showed how sympathetic irritation may produce intestinal stasis which must increase putrefactive changes. The opposite condition, hypotension, is seen in Addison's disease, the symptoms of which may be explained in the light of the cooperation between the adrenals and the sympathetic. In wound shock the low blood pressure is probably due to capillary stagnation. Cannon has therefore suggested the revival of the Hippocratic term "exemia," for the shocked man is "drained of blood" into his capillaries. Recent observations by Dale and Richards have shown that capillary dilation may also occur from purely toxic action. This would seem to necessitate a revision of the current theory, according to which the effective peripheral resistance is in the arterioles, that in the capillaries being negligible, and the author points out that the effect of all this work is to dethrone the vasomotor system, and therefore the sympathetic, for the position of autocratic control of the circulation. Finally, the author expresses the hope that in these lectures he has been able to make clearer the influence of the mind on the body, even though stated in terms of current physiology and without reference to psychological factors.

3. Intravenous Injections of Antimonium Tartaratum in Kala-azar.—George C. Low reports a case of kala-azar which is of special interest because the infection was acquired in Bagdad, where the disease does not apparently exist indigenously, because it is the first case the author knows of which has been treated in England by intravenous injections of antimonium tartaratum, and because an unfortunate attack of influenza, by carrying off the patient just at the termination of his treatment gave an opportunity of definitely determining whether or not a complete sterilization of his *Leishmania donovani* had taken place. The patient who had lived all his life in England joined the Army at the end of 1916 and arrived in India in March, 1917, and in Bagdad on July 30, 1917. He was taken ill the following March and was invalided to England at the end of August, 1918. Tartar emetic, intravenously, in small doses was begun in October, when the author saw him. In November he came under the charge of the author, who pressed the antimony as patient was depressed and ill and still running a high temperature. After the first big dose of 2 grains the temperature fell and never rose again, with exception of a rigor once or twice after some of the injections, and by Feb. 10, 1919, patient was apparently in perfect health, was eating and to all intents and purposes was clinically cured. The attack of influenza commenced two days later, death occurring on the 17th. At post-mortem there was complete absence of *Leishmania donovani;* the liver showed a well-marked cirrhosis, was double the normal size, and to the naked eye was yellow and distinctly fatty—microscopic examination of sections of the liver revealed considerable fatty infiltration of the parenchymatous cells and fibrous changes of a somewhat irregular type; and cloudy swelling and fatty changes were observed in the kidneys. Other viscera showed no signs of importance. The author suggests that these fatty changes, which have been observed in the few cases of this disease which have come to autopsy, might quite well have disappeared if the patients had not been carried off by intercurrent disease, and it is very likely that all cases show these changes to a certain extent but recover from them when the drug is stopped. The degree of fatty change in the liver is much more extreme in ankylostomiasis, yet some of these cases recover perfectly once the parasites have been removed. What is required is a test to determine when the leishmanial parasites have disappeared, so that the injections could be stopped when they can do no further good but may do considerable harm. The author concludes that: (1) Antimonium tartaratum is a specific against *Leishmania donovani*, and in the case under discussion sterilized the patient of his infection. (2) Antimony in large doses, given over prolonged periods of time, produces fatty changes in the liver and kidneys, which may seriously damage the resisting powers of the patient, and may even cause death (as in the case of an aboriginal Australian suffering from ulcerating granuloma reported by Breinl and Priestley). (3) Antimony should not be given for longer periods than necessary, and therefore it is important that some definite test should be evolved which will indicate when the infection of kala-azar has disappeared and the patient is cured. (4) If the antimony is finally proved to destroy the *Schistosoma haematobium*, then a similar test to determine when the destruction has taken place is required. (5) In all cases where antimonium tartaratum is given intravenously the patient should be confined to bed on the day of the injection and kept there till the day after, and should be carefully watched throughout the course, any indications of gastric or constitutional disturbances at once contraindicating further injections. (6) Not more than two injections a week should be given, and the salt should not be given in too concentrated a form.

Berliner klinische Wochenschrift.

March 31, 1919.

Bacteriological Findings in Typhus Fever.—G. Bessau has found in cases of pneumonia complicating typhus fever, rod-shaped organisms of the type of Pfeiffer's bacillus. They offer the microscopic and culture characteristics of the latter organism. These findings were made at a time when influenza did not exist. Besides the cases of pneumonia, the writer was able to grow from the blood of typhus fever patients, a rod-shaped bacillus having two very small poles and stained best with a dilute carbolic fuchsin solution. Their presence was established in about 90 per cent. of the cases. The writer points out that these organisms have already been described by many writers in various countries, in the shape of Gram negative bipolar rods. Unfortunately, he was unable to make serial cultures as the bacterium could not be obtained while still motile. Beside these concording observations of various writers are the findings made on lice in which parasite the Richettsia has been found which organism would seem rather to belong to the group of protozoa. Although they have not been identified in the blood of patients, very strong experimetal arguments nevertheless attribute an important part in the spread of typhus fever to them. These two series of facts lead the writer to ask the question whether or not these two micro-organisms are not in reality a single one which varies in aspect according to the host it inhabits.

The Indications of Manual Detachment of the Placenta When the Latter Is Adherent.—W. Liepmann reports two cases of retained placenta which could be expressed from the uterus ten hours after labor. These two cases brought up the question as to whether or not it is correct to interfere, even when there is no hemorrhage, during the first few hours following labor. This manner of procedure (most writers give from three to six hours as the time before interfering) offers a considerable operative risk which makes legitimate any attempt to avoid all intrauterine manual work.

The Causes of Circulatory Weakness in the Purely Pneumonic Types of Influenza.—W. Frey states that weakness does not result from a failing cardiac action because no venous stasis is observed. In reality, the condition is one of vascular atony which should be above all treated with camphor and caffeine. Digitalis should also be used as an accessory in the treatment.

Münchener medizinische Wochenschrift.

March 28, 1919.

The Differentiation of the Bacilli of Malignant Edema.—H. Schlossberger maintains the idea of a very close

relationship existing between the different anaerobic agents which can give rise to gas edema. This relationship is illustrated by the case with which these various strains give rise, in broth media, to filtrate hemolytic substances. The hemotoxins collected by the writer from some fifty different strains derived from cases of maligant edema and morphologically very unlike, offer an absolute similarity. On the contrary, he was unable to establish the ratio existing between the virulence of the strains and the quantity of hemotoxin formed. The writer was able to immunize rabbits against this hemotoxin and he also noted that the fixation of the hemotoxin by sera thus obtained obeyed the law of multiples. The serum of an immunized rabbit neutralizes exactly in the same way the hemotoxins derived from the most divers strains of cultures obtained from cases of malignant edema. It is more especially upon this that the writer comes to the conclusion that "in the various types of agents giving rise to malignant edema we are dealing with closely related species, perhaps even varieties, subspecies or aberrant forms of a single bacterial species."

Late Thrombosis and Gangrene Following Congelation.—E. Nägelsbach gives a review of the literature of this subject and studies a personal case which leads the writer to the conclusion that in congelation the arterial thrombosis plays an important part. It may end in gangrene after an interval of several months. The veins do not participate in the process.

Insufflation of Carbonic Acid in Artificial Pneumothorax.—C. Wiedemann points out that the danger of this operation resides in gas embolus by injecting the pulmonary veins. Therefore, the writer proposes the use of CO_2. The advantage of this procedure resides in the fact that the arterialized blood in the pulmonary veins can dissolve a quantity of carbonic acid twenty times greater than of oxygen. The writer's essays seem to show that this gas does not have any irritating action on the pleura, while on the other hand, its absorption is relatively rapid, a fact which limits its use to the first injections.

Deutsche medizinische Wochenscrift.

March 27, 1919.

Experimental Studies on Typhus Fever.—B. Möllers and G. Wolff state that in intraperitoneal injections with Bacillus Proteus ₊19 do not immunize guinea-pigs against typhus fever. Therefore, this bacterium is not the etiological agent of the disease. The guinea-pigs inoculated with typhus virus do not give the Weil-Felix reaction. On the other hand, this reaction is obtained in guinea-pigs inoculated with Proteus ₊19. The typhus virus is present in the blood and all the viscera during the disease. Incubation varies from five to twenty-one days in the guinea-pig. Inoculation of this animal confers immunity, but the question of immunization with dead or attenuated virus is not as yet solved. Animals weighing from 200 to 300 grams are more difficult to inoculate than those having a lesser weight.

A Case of Mitral Insufficiency with Good Functions of the Right Ventricle, Recognized by a Venous Pulse.—R. Ohm recalls the type of venous pulse which corresponds with the asthenia of the right ventricle, namely, it is characterized by the absence of diastolic depletion of the jugulars (see *Deutsche med. Woch.*, No. 42, 1918). On the contrary, a well-compensated mitral lesion, such as the case reported by the writer, shows a rapid drop of the venous pressure during diastole. This type of venous pulse corresponds to a ventricle which empties itself well at each systole and exercises a strong aspiration during diastole.

Eosinophilia of the Blood in Muscular Rheumatism.—H. Bittorf describes an eosinophilia in this process which may reach from 5 to 12 per cent. and disappears at the time of amelioration or recovery. This symptom is sufficiently constant to be used in the differential diagnosis between hysteria, anemia or simulation. It likewise confirms the inflammatous, toxic or diathetic nature of muscular rheumatism and speaks against a purely neuritic origin of the affection. The writer is inclined to consider the eosinophilia as being produced by a disturbance of the metabolism of the muscular tissue.

Le Progrès Médical.

April 19, 1919.

Cold and the High Cost of Living.—Lortat-Jacob discusses this problem as it affects Paris and France. Paris consumes annually 235,000,000 kilos of meats of all kinds. Butchers' meat shows the most marked tendency to decrease in favor of poultry, game and preserved meats. There is also an increasing tendency to eat the flesh of young animals and as a result there is in the market less beef and mutton and fowl. The older animals also die off in large numbers from special diseases. These conditions were prevalent long before the war. To offset this disappearance from the market of certain meats refrigeration was introduced with especial reference to transportation from great distances. Tellier, a Frenchman, as is well known, was the founder of this movement which tended to do away with the local use of ice as a preservative. Conditions in grazing countries naturally stand in close association with the export trade of meats. In some of these countries the animals are really killed for leather and the flesh was a mere by-product. Refrigeration is also largely used to conserve and transport milk and fruits. The dairies of Jutland, for example, can transport fresh milk intact to points 48 hours away by ordinary carriers. Transportation of meats, eggs and milk is markedly individualized and we do not apply the technique of one business to another. Beneath all of these aspects of business there is a rationale. Meats are conserved because a special range of temperature known as "great cold" can exert a definite action on the protein. But it is also true that in practice minor cold or refrigeration temperature can also conserve meat over a long interval. Moreover refrigerated meat is not denatured, as shown by tests of all kinds. The problem, however, is not quite so simple, for the cold used must be free from moisture—dry cold in the strict sense of the term. If this precaution is not fully maintained the meat will have a peculiar taste and in general will be moldy. In regard to milk, we have to consider pasteurization, freezing and refrigeration as methods of conservation. Objections to the former are well understood and described in all textbooks. The uses of freezing are quite limited. Refrigeration, unlike the other methods, does not denature the milk while it guarantees when freshly applied a good degree of preservation.

Hygiea.

March 31, 1919.

Nutrition of the German People Under War Conditions.—Johansson says that up to the close of 1916 the following conclusions were borne out by figures. Living under free conditions healthy adults of any age between 20 and 60 were up to their usual efficiency, although leaner than before the war. But many of sedentary and confined occupation, others who had to live on small fixed incomes, and others again unequal to full work activities as well as brainworkers showed corporeal weakness and decreased capacity for work. Invalids of from 20 to 60 leading out of door lives showed a supernormal mortality from various disease groups. The mortality in all people over 50 was heightened. The country and small town man stood a better chance for survival than the urban dweller. Tuberculosis mortality is very greatly augmented.

Mode of Diffusion of Influenza.—Ehrenberg wonders whether a study of diffusion of influenza in an institution can furnish a lead as to the nature of pandemic diffusion. In the Provincial Hospital at Falun during the last pandemic wave 143 patients of all kinds were cared for. Whether any of these were admitted for this affection is not stated, but every victim was isolated from the other patients. These latter furnished natural controls for the attendants, who were of course freely exposed in the influenza wards. Result: not a single transmission among the protected patients and 90 per cent. of transmissions in the exposed attendants. In connection with this fact there are others which show that bedfast patients are often immune in influenza episodes, but this can only be due to lack of exposure.

Book Reviews.

THE WHOLE TRUTH ABOUT ALCOHOL. By GEORGE ELLIOT FLINT. With an Introduction by Dr. ABRAHAM JACOBI. Price $1.50. New York: The MacMillan Company, 1919.

IT is unfortunate that the author of this book did not have an opportunity to revise some of his text after the adoption of the prohibition amendment for he repeatedly expresses himself as believing that such an amendment could not be adopted. It is also unfortunate that his book did not appear and find a wide circle of readers, a year or more ago. Although not a medical man himself, the author is of a medical family and has a satisfactory understanding of physiology and medical literature. He is thoroughly familiar with his subject and is not afraid to present all of the data available. He hammers relentlessly at the universal practice of the prohibitionists, as indeed of all fanatics, the anti-vivisectionists for example, of spreading abroad half-truths. This is the most dangerous form of propaganda, one that the Huns practised energetically. The book lacks somewhat in coherence at times, which is apparently due to the fact that the writer becomes thoroughly stirred up, and pardonably so, on reading some of the literature which has been published in favor of prohibition. He exposes the fallacies supported by Sir Victor Horsley and others and on the whole presents all aspects of the question. He perhaps does not emphasize the essentially un-American nature of the amendment as much as we would like to see him do, but we feel that no unbiased reader could fail to be convinced by his arguments. The book has appeared too late to help us, but the reader will find it not only interesting but full of information that may be relied upon as scientifically accurate.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia. Assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. March 1, 1919. Price, $6.00 perannum. Philadelphia and New York: Lea and Febiger.

THE first chapter of this number contains a review of the surgery of the head, neck and breast by C. H. Frazier; it is largely, though not entirely, concerned with "war surgery," and is both interesting and valuable. Surgery of the thorax, excluding diseases of the breast, is by G. P. Müller, and contains a summary of the surgery of the heart, the lungs and pleuræ. J. Ruhräh contributes the chapter on infectious diseases, including acute rheumatism, croupous pneumonia and influenza; a noticeable feature is the section on trench fever. The remaining chapters are by F. M. Crandall on diseases of children, and G. L. Richards on rhinology, laryngology and otology. The whole number is of permanent value to all who are trying to keep abreast with the times.

LENZMANN'S MANUAL OF EMERGENCIES, Medical, Surgigal and Obstetric. Their Pathology, Diagnosis and Treatment. (Based upon Lenzmann's "Emergencies in Medical Practice"). By J. SNOWMAN, M.D., M.R.C.P. (Lond). Price $4.50. New York: William Wood and Company, 1919.

THIS Manual is based upon the English edition of Lenzmann's "Emergencies," which appeared in 1914. The original scheme has been closely followed but the text has been entirely rewritten and the subject matter extensively revised so that it is essentially a new work. It is possible to object that some of the subjects treated of are not really emergencies but they may appear in that manner and all properly belong within the scope of this work. One of the things which attracts the notice of the American reader is the differences between English practice and our own. In laryngeal diphtheria, for instance, the antitoxin dosage recommended is 2000 units for infants and 5000 units for adults, certainly much less than we should use in an emergency of this nature. Also the author seems to prefer tracheotomy to intubation. The dose of digitalis recommended in various places is much less than that we have come to consider an effective amount. The intravenous use of tetanus antitoxin is declared "inadvisable" because of the danger of anaphylaxis, and yet in another place the author shows how it is possible to avoid this danger. On page 258 the author speaks of making the blood "hypertonic" by infusion with "physiological salt solution," which is, of course, a simple error. In his discussion of diabetic coma he gives a very crude test for an excess of sugar in the blood which is no simpler than the Lewis-Benedict method, the present standard method. He also gives none of the blood tests for acidosis. In discussing transfusion he makes no mention of the use of citrated blood, a method which is the one most frequently followed in the United States. But all of these points are largely differences in practice and do not necessarily constitute a damaging criticism of the value of the work as a whole. In it the reader will find directions for the diagnosis and treatment of nearly all the emergencies which are of sudden origin and which threaten life and find them so detailed that rapid comprehension will be easy. It is a convenient book to have at one's elbow in time of need.

AMBULANCE DE "L'OCÉAN" LA PANNE. Tome II. Fasc. I. Juillet, 1918. Travaux publiés sous la Direction du Dr. A. DEPAGE. Paris, 1918.

THIS number contains thirteen papers on military surgery and pathology of the types heretofore published. Eight refer directly to wounds in various localities, four to bacteriology of wounds two to methods of treatment, etc. There are over fifty figures and charts. Apparently none of the papers has any pioneer or other special significance. The volume has the force of any hospital report.

THE SURGICAL CLINICS OF CHICAGO. Vol. II, No. 6. December, 1918. Octavo of 204 pages, with 63 illustrations. Published bi-monthly. Price per year, $10.00. Philadelphia and London: W. B. Saunders Company, 1918.

THERE are nine contributors to this number and each has furnished material well worth reading. The more important case reports and clinical lectures, in our opinion, are Bevan's clinical lectures on a very rare case of acute necrosis of the right lobe of the thyroid, a case of ruptured urethra, and a complete description, with illustrations, of his method of operating for undescended testes; Kretschmer's lecture on hæmaturia and purpura; and McArthur's discussion of a case of fibromyoma of the stomach simulating, in its symptomatology and radiographic findings, ulcer of the stomach. Watkins describes what he calls a "simple and efficient operation" of perineorrhaphy. The article is well illustrated and the operation certainly seems simple and, theoretically, appears efficient. Those interested in the surgery of the nose and throat will also find an instructive discussion by Shambaugh of clinical problems relating to faucial tonsils. An index, covering material in the various volumes for the year, is appended.

MILITARY SURGERY OF THE EAR, NOSE AND THROAT. By HANAN W. LOEB, M.D., Major Medical Reserve Corps, U. S. A. Medical War Manual No. 8. Price $1.25. New York: Lea & Febiger, 1918.

Of the 176 pages of this work no less than thirty are devoted to bibliography which strikes one as extraordinary for a compressed pocket manual. The subject matter consists chiefly of the management of injuries of the various structures with special chapters on psychoneuroses reconstruction and rëeducation, paralysis, larynx stenosis, simulation, aviation tests and numerous miscellaneous topics.

ELEMENTARY BACTERIOLOGY AND PROTOZOOLOGY FOR THE USE OF NURSES. By HERBERT FOX, M.D. Director of the William Pepper Laboratory of Clinical Medicine, etc. Third edition. Thoroughly Revised. Price $1.75. New York. Lea & Febiger, 1919.

In the absence of access to the earlier editions we are unable to give a complete review of this volume and must depend on the preface. The work is said to have been thoroughly revised and to incorporate considerable matter of military significance. In writing for the nurse the author is practically writing for the laity and in this edition has emphasized this viewpoint in both theoretical and practical aspects.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Seventieth Annual Session Held at Atlantic City, N. J., June 9, 10, 11, 12, and 13, 1919.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 43.*)

SECTION ON THE PRACTICE OF MEDICINE.

Second Day—Thursday, June 12.

The Clinical Study of Pulmonary Excursion.—Dr. CHARLES F. HOOVER of Cleveland, Ohio, presented this paper. He said that the study of excursions of the thorax was a phase of clinical examination which was too lightly treated, but it was extremely important to seek for more confirmation of disease of the lung. In making a diagnosis attention was directed to three phases: volume, density, and extensibility of the lung. Less disease was required to modify extensibility than the other two phases, therefore this attribute was the earliest found. A guide to this would be the observation of the normal excursion of the second, third, and fourth ribs; the third was larger than the second, the fourth than the third. Disparities in this would be detected and an undulatory movement was seen before other evidence of tuberculosis was found, either by percussion note or respiratory sounds. Excursion of the costal margin would give evidence of volume of the lung and confirmation of flattening of the diaphragm. In inspiration the costal margin moved away from the median line through the movement of the intercostal muscles, but with flattening of the diaphragm there would be modification and narrowing of the subcostal angle, instead of widening, at inspiration, as in the case of enlarged heart. Symmetry and asymmetry of the costal margin should therefore be studied. The intercostals were important in the ventilation of the lung; although with intercostal paralysis a man lying down might breathe comfortably, on exertion there would be extreme respiratory distress. In one case of this sort a child two and a half years of age, with paralysis of the six upper intercostals, the alveolar air was pushed back and forth from the upper to the lower part of the lung. No method of examination would give so much information of the extensibility and volume of the movement of the lower portion of the lung as the study of the movement of each rib.

Dr. SEWALL of Denver said that Dr. Hoover had opened a new field in the clinical physiology of respiration. Since Hutchinson's work in 1834 on residual pulmonary air, little had been learned. He, personally, had published a paper on the relation of the diaphragm to costal respiration, and had learned enough to see that there was a tremendous unexplored field in the subject. This was as yet uncovered. The rate of the blood flow through the lungs was of supreme importance. In one case the blood went through two or three times the volume that it did in another person, and in changes of position there was a volumetric pull on the blood which did not go back to the heart. Faintness from blood ptosis could be counteracted by flattening and contraction of the abdominal muscles. In regard to one part of the lung pumping blood into another part, this could be demonstrated by holding the breath long, closing the glottis and contracting the abdominal muscles. The blood could be churned back and forth. This could be tried in the surf when one was pretty nearly suffocated. Physicians had avoided the subject of the mechanics of respiration, but they were just as important as the signs of appendicitis.

Dr. CHAS. L. MINER of Asheville, N. C., said for many years he had believed that the presence of a small focus in the upper portion of the lung would manifest itself by contraction of the base, as much as in any other way. Percussion was of more value here than fluoroscopy, as it showed the rise and fall of the dome of the diaphragm. If one had an early development in the apex or marked limitation of the base, it was of great early diagnostic value. With the focus lower down one could tell whether the motion of the base was limited in front or behind. Ransome's stethometer would measure the local motion of the second, third, and fourth ribs. The society was indebted to Dr. Hoover for advancing the art of physical diagnosis. These little refinements brought out important points. Diagnosis of tuberculosis was the summation of many fine points and built up of many small factors.

Dr. C. F. HOOVER, in conclusion, said that the phenomenon Dr. Sewall had mentioned in holding the breath was difficult to explain. If the lungs were superventilated for five or six inspirations, and the glottis closed, then if a deep breath were taken one could not hold the breath for more than 20 seconds. On exhalation the concentration of CO_2 would be 6.3; but, if one ventilated the lung with pure oxygen the breath could be held longer, on account of the rise of CO_2 in the aortic blood, which would amount to 9.3; therefore the concentration of carbon dioxide must balance the alveolar air. With reduction of oxygen one could not hold the breath. There was no rational explanation of why there was a tolerance of CO_2 in the presence of excess oxygen. The shortness of breath was not explained at all. In regard to the pleural sinus, this was often emphysematous, without emphysema of the whole lung.

Chronic Arthritis in the Army; Observations Based on a Survey of Four Hundred Cases.—Dr. RALPH PEMBERTON of Philadelphia presented this topic. The Surgeon General provided for the study of arthritis, and a large series of cases was undertaken. In an army of four million there were 30,000 cases, or perhaps more. The statistics presented embraced 400 cases: 64 per cent. were pure arthritis; 28 per cent. combined with myositis; there was a history of long exposure to wet or cold in 58 per cent.; dysentery, 8 per cent.; influenza, 7 per cent.; gas, 6 per cent.; 36 per cent. had had previous attacks. The knee was most commonly involved (as in civil life); the shoulder as often as the ankle and hip. Cases were examined for a surgical focus, and it was demonstrable in 293 cases, half of these being in the tonsils. Fifty cases were due to genitourinary infection, but there was no Neisser infection. Forty-six cases recovered in apparent presence of the surgical lesion. These cases seemed independent of the foci. Twenty-three cases without surgical foci recovered. Basal metabolism studies were started; this was normal in 80 per cent. The CO_2 combining power of the blood gave normal figures, as did the blood nitrogen and urea figures. There was no important disturbance in fats or cholesterol. Calcium was normal. In regard to diet, there was a clear cut relation to the food intake in many cases and the carbohydrate metabolism was found involved. Sugar tolerance was then studied, and the percentage concentration of dextrose in the blood after 100 grams dextrose was estimated. Severe cases of arthritis were not able to remove sugar from the blood as did normal individuals; mild cases showed less disturbance. This disturbance was not specific for the disease, but related to some physiological process not understood. Renal function was a little subnormal in regard to water, salt, and nitrogen elimination. Creatin and creatinin in relation to carbohydrate metabolism were studied, and were found above normal level in the blood and fell as the individual improved. It seemed that arthritis cases recovered in proportion as the carbohydrate metabolism was regulated.

The military aspect of these cases was important, but the soldier overseas responded better to therapy than did the patient in civil life. This was because cases could be segregated, infections could be removed, massage, hydrotherapy, and diathermy could be instituted.

Dr. FRANK BILLINGS of Chicago said that just such studies as these would finally reach the truth concerning arthritis. There were two points in reference to the etiology; one was the statement that a large number of men recovered without any attempt upon the surgical foci. This would seem reactionary. The principles of infections must be applied. The organism might reach a virulence which overcame the immunity of the host. Immunity was never absolute, but relative, and exposure to wet, cold, and fatigue lowered the level and permitted organisms to attack the host. The very

fact that foci were present, therefore, did not mean that they were at the stage of virulence to overcome immunity. Immunity was no doubt improved by hospital treatment. The second point was the relation to basal metabolism. This branch was in its infancy, and little was known as to how to apply the principles of metabolism to any treatment. Regulation of the diet had a direct effect. In regard to treatment, the rational recognition of foci of infection meant their removal. Many people no doubt went too far and removed everything in sight which appeared infected. In the patient the basal metabolism had doubtless been disturbed for a long time, causing lowering of condition. Principles could not be applied wholesale, but individualization must be made. Massage, heat, hydrotherapy, diathermy, what were all these methods but the improvement of local circulation and incidentally metabolism. Removal of foci and regulation of metabolism constituted rational treatment.

Dr. E. P. Joselin of Cambridge, Mass., said that he was sorry he had not heard the first part of the paper; he realized an enormous amount of work had been expended on these studies.

Dr. L. A. Conner of New York said many points in this paper deserved attention. The war hospital laboratories had given much facility for investigation of this type, and one could see the result here. In the study of arthritis a start could be made from this point which marked an epoch in the investigation of the disease. One surprising point was the insignificance of gonorrheal infection in this group, and at an age when one would have supposed it would play a leading part.

Dr. Pemberton, in closing, said that focal infection was not ignored; in fact, it was the basis from which a start was made. Still, many cases did not get well after removal of foci. Lowered tolerance of sugar might also persist after removal of foci.

The Psychic Factor as an Element in Temperature Disturbance as Shown by Some Observations in the Selective Draft.—Dr. Frank B. Wynn of Indianapolis presented this paper. As a member of the draft board, the author had made an interesting discovery. Of 3,500 draft applicants no particular note was taken as to temperature until a disputed case was noted, in which the man claimed to be tuberculous. He was granted an exemption on the ground of the rise of temperature (101) which he showed. After this the remainder, 324 cases, were observed in this respect. Sufficient information was obtained to warrant this paper. In splendid young fellows, in tiptop condition, temperatures of 99° or more were noted with frequency. It would seem that fever and elevation of temperature were hardly synonymous. Elevated temperature unaccompanied by physical signs must be recognized. Physiological rise of temperature could be observed in men and animals during exercise, taking of food, and change of posture. Monkeys had a diurnal temperature curve, and man to a less degree. This was a matter of heat production and heat dissipation. The influence of psychic states, such as suspense, upon temperature was found to be very definite. Of 320 soldiers only one-sixth showed normal temperature; two-thirds were above, one-sixth below normal. This was during the suspense of examination. The men presented a fairly uniform mental complex in which suspense predominated. The psychic tension evidently retarded heat dissipation and increased muscle tone and body metabolism. In a group of nurses undertaking their graduating examination the same phenomena were noted, but to a less degree. It would be well if physicians would be on the lookout for this type of thermal elevation, which might be produced by the mental state, plus afternoon increase of metabolism.

Dr. C. D. Humes of Indianapolis said that this paper showed much careful experimental knowledge. The nervousness of men about to enter army life, the tension of nurses about to take examinations to start them in their life work, presented about the same mental picture. When one carried in mind the picture of the overactive thyroid, the leaky skin, cold hands, active peristalsis, one wondered if the temperature were associated with glandular secretion. The temperature variation was pretty constant in those considered unfit for military service. In the neurological center at Savigny, from March to June, 1918, the types observed of neurological misfits usually ran an elevation of temperature. It was an unusual thing, however, to see men come out of the fighting line having a high temperature. Exhaustion did not cause it. Fear, apprehension, and homesickness formed a definite mental picture. If it was denied that there could be a rise of temperature from these causes it would be denied that men could die from homesickness, but this could also happen.

Dr. F. M. Pottinger of Los Angeles said that if one could get away from the fact that an absolute normal existed, it would help greatly with different individuals. Eighty-five per cent. of heat was dissipated through the skin by vasomotors under the sympathetic control. When patients came for the first examination a half to one degree of variation could be allowed. Undoubtedly a nervous element existed, which caused stimulation of the vasomotors. In women the temperature immediately before menstruation was apt to be higher than after. It would be found to be 99° for as much as fourteen days premenstrually. It was an error to suppose that every patient with a slight rise of temperature had tuberculosis, nor was it true that the patient without temperature did not have tuberculosis. More harm had been done by depending upon this temperature evidence than by any other factor in diagnosing tuberculosis. Other corroborative factors must be sought. Physiological rises of temperature were to be noted, as, for instance, in exercise in the hot sun. This was normal. In pathological conditions the control of the blood vessels and temperature remained longer.

Dr. E. Libman of New York said that the question was an important one. Quite a number of cases gave febrile reaction without foci of infection. The profession did not realize this point to the full. Besides infections as a cause of temperature one could enumerate disturbances of the ductless glands, those due to cerebral cases in which there was disturbance of the sympathetic nervous system. Other observations might be cited, as the pressure on the peritoneum in disturbance of the liver. There was an alteration of metabolism without presence of bacteria, but a rise of temperature occurred. As soon as there was evidence of foreign substance in the circulation hemolysis occurred, and the temperature rose. In cases of blocking of the ureter, especially with stone, where a collection of the urine occurred behind the stone, there was a sudden rise of temperature. The premenstrual temperature sometimes led to mistakes; in one patient appendicitis was suspected on this account, but was not found. In thyroid hyperactivity and ductless gland disturbances an elevation of temperature was present. Osler had described a series of cases in which there was no infection but a very high temperature. In cerebrospinal meningitis, after the meningitis had run its course and there was a distention of the ventricle, the patient was apt to have high temperature; this was also true of cases after lumbar puncture, even when there was no infection.

Dr. H. Plummer of Rochester, Minn., thought what Dr. Pottinger had said was interesting, that temperature was the equilibrium between heat production and elimination. On the whole it had more to do with elimination than production. If elimination were not interfered with production could be raised 100 per cent. above normal, as by the thyroid hormone, and leave the temperature normal. With great flights of heat production the temperature was hardly raised one degree.

Dr. F. B. Turck of New York said that this was a biological question and subject to exact experimental methods. This was studied by introducing tissue into the stomach, skin, bowel, and then interrupting circulation in the leg. Autolysis of tissue occurred and wherever autolysed tissue reduced the circulation antibodies caused rise of temperature. The injection of autolyzed tissue gave an instant rise, whether produced by toxin or interrupted circulation or by slow digestion of tissue. Thus an exact answer to the question could be given. Autolysis of tissue caused a rise of temperature and a fall in blood pressure would restore temperature to normal. These were the scientific facts.

Dr. J. Head of Minneapolis said that all these observations upon so-called normal had not been as care-

fully controlled as they might be. Statistics showed that many young men, after repeated examination by local boards, went into service and one year later were returned as active tuberculosis cases. No matter how well a young man or woman might look, no scientific observations as to temperature reactions could be made without checking them by a specific dose of tuberculin to see whether or not the subjects had tuberculosis.

Dr. WELLS of Chicago said that in local draft board work he had noted many cases of temperature running from 99° to 102°. This, however, could not be psychic, because it was observed in the same individual several times.

Dr. WYNNE, in closing, said that even granting the contention of Dr. Turck that the disturbance was biochemical, that did not dispense with the etiological factor. The cause of that was suspense plus anxiety. With muscular hypertonus, plus physical exercise, plus increased metabolism, there must be biochemical change. Behind this was the psychic factor. Physicians who associate temperature curves with fever forget the physiology of heat control. Variation in muscle tone equals heat production. Vasomotor and skin control equal elimination. The fact that psychic states could influence temperature should make physicians careful in making diagnosis unless influencing factors be clearly kept in mind.

Importance of Physical Development in Cases of Effort Syndrome.—Dr. B. SMITH of Los Angeles, Cal., presented this subject. The military manual of exercise proved useless in the cases of effort syndrome, with physical and general muscular weakness. The sharpness of command did away with the good effect. A course of graded exercise resulted in great benefit to the men and put them on a better economic status. The armistice was signed a little too soon to try them in military life. A very small percentage of these men showed definite defective intelligence, with no ambition, only a few of these were seen and they were hopeless from a military point of view. In others intelligence was keen, they were often college students; there was, however, a neurotic element noted. These improved steadily, and if even one man was brought up from a poor worm to a being with self respect, the work was worth while. Most of these men needed psychiatric attention plus the physical help. The men who broke down in the front line trenches were built up again very readily. The cases that follow ordinary infections were included, but not those following acute rheumatic fever. These cases as a rule showed persistent myocardial damage.

Dr. E. W. BRIDGEMAN of Baltimore said that he had worked with Lewis in England and had then gone back to France. He had seen about 5,000 cases of effort syndrome. Lewis had instituted graduated exercise for the purpose of classification and treatment. The same course was applied in the American Army, and 91 per cent. were sent back to front line duty. One per cent. were classed for lighter duty. These men came in with all types of diagnosis. Some were sent to the neurological center for war psychoses, some to the cardiovascular specialist. The symptoms described depended upon the specialist who saw them, but they were, in the main, about the same. Effort syndrome was assumed from the symptoms. Prophylaxis was of distinct importance. In many cases insufficient time had been allowed for recovery from acute infections. If sufficient time for convalescence were allowed effort syndrome was prevented. Tonsilitis required 34 days; mumps 39 days; herniotomies 50 days. These figures were higher than the usual ones. There were individual variations in classes of men as seen by track athletics. The sensitive, nervous dash men had to be trained differently from the long-distance, plodding type. The man doing long distance runs was not able to be a sprinter. The army routine compelled all sorts of men to do the same kind of work, with the result that the nervous dash type of men developed effort syndrome. Two facts were made clear. Effort syndrome was not a disease entity, although it might be found with organic disease; prophylaxis was developed by prolongation of convalescence from acute disease.

Dr. W. S. THAYER of Baltimore said that this subject was likely to be the most important medical outcome of the war—the direction of attention to care of subnormals and the prolongation of convalescence. In regard to the latter, the profession had lost its sense of responsibility. The convalescent was his own master. For the first time the Government had stepped in and demanded that the convalescent be helped back and rehabilitated. What was being done at the convalescent camps was of the greatest importance. In regard to tonsilitis, it was found that healthy young men were not fit for duty for 34 days. That gave something to think about. One asked oneself how much endocarditis could have been prevented if one had held on to patients during their convalescence. If the profession would learn how to care properly for their convalescents it would be one of the greatest outcomes of the war.

Dr. SMITH, in closing, said that they all felt that if the armistice could have been postponed for a few more months, without hurting anybody, it would have been a great thing. He had never been an enthusiast about physical development until he had seen this graded work. This was very important to physicians in certain lines. Orthopedic cases, neurotics, pulmonary cases, cardiopaths, were all benefited. Many cases with long continued symptoms before entering the service and who showed early physical fatigue were greatly improved. Strength tests were used to check up results. The only men that failed to respond were those with lack of ambition. The convalescents showed that at least six weeks were needed to return men to full work.

Pericarditis as a Complication of Pneumonia, Based on Three Hundred Necropses.—Dr. WILLARD J. STONE of Toledo, Ohio, presented this topic. The speaker said that there was not much literature in regard to pericarditis with pneumonia. In 15 per cent. of pneumonia cases autopsied an acute purulent pericarditis was found, the maximal amount of pus observed being 350 c.c. It was found that the fibrinoplastic type was almost impossible to diagnose. Acute suppurative, fibrinopericarditis occurred most frequently when both lungs were involved, and the same was true of the purulent type. In bilateral empyema cases, 23.6 per cent. developed pericarditis, and this appeared to be the most important factor in its development; 31.2 per cent. of cases dying after empyema operations were found to have had pericarditis. A diagnostic sign was the percussion sound heard over the base of the heart in the 4th to 5th interspace, close to the sternum, synchronous with the heart beat. In marked effusion the area of dulness changed. The *x*-ray was found to be of great help in the diagnosis of walled-off fluid, except in cases where a very small amount had accumulated. In every empyema patient who presented septic temperature pericarditis was suspected, and it was found that in only two cases of empyema pericarditis did not exist. In treatment, paracentesis was used by free incision and drainage, the incision being made under local anesthesia. Care was taken in the insertion of the needle, a point being chosen outside of the nipple, in the left 4th interspace, directing it backward toward the spine, so that there was no danger of puncturing the myocardium. Another point of insertion was immediately beneath the costal margin, in the angle of the xiphoid, with the diaphragm in the normal position, the needle pointed slightly to the left and above the nipple. Ice bags and morphine were used to control pain. Antistreptococcus vaccines were often employed. In 75 per cent. of the cases a hemolytic streptococcus was isolated.

Dr. C. W. WILLIAMSON of Chicago said that he had been endeavoring to get nearer to the solution of the problem of this, the worst complication of pneumonia, by injecting into the pericardium of the cadaver some coagulable substance such as agar, by means of which a cast was immediately made. In one case it was found that pneumonia had cleared up, but the great veins at the base of the auricles had completely collapsed. The particular point emphasized by this finding was that the amount of fluid was not the only indication for carrying out the puncture in pericarditis (as was stated in the text-books); but in many cases where there was a distinct pericardial rub one should become suspicious, even if the amount of exudate was small. In one such case the difference of a small amount of fluid had caused collapse and death of the patient. A small incision was made at autopsy in the left costo-xiphoid angle and 270 c.c. of fluid alive with pneumococci was

withdrawn. He had seen the same thing with 400 c.c. and he was sure it was common. One should not wait for great big effusions. However, there was one point to bear in mind; this was the rapidity with which the effusion was poured out; if very rapidly, it caused death by mechanical embarrassment. Puncture was imperative to save life.

Dr. CHARLES F. HOOVER of Cleveland said that there were several indications to determine whether one should do paracentesis or not. Men were called upon to see endocarditis and myocarditis as well as pericarditis. One had to study the output of the heart, and to inquire if the myocardium was failing or if the pressure of fluid was rising in the serous sac. In many cases one would leave the sac alone, were one certain that one was dealing with impairment of the myocardium. How was that point to be settled? The flattening of the diaphragm might be the same in both. Pericardial fluid would not encroach on the large vessels and impair diastole without inspiratory narrowing of the sub-costal angle. Thus after drawing 500 to 1500 c.c. the behavior of the sub-costal angle was noted. It would be observed that, in the patient suffering from impairment of the heart from pressure of the pericardial sac, the lips would be pallid. Cases with myocardial involvement did not show this labial pallor. This was of diagnostic importance. Another point was that as the pericardial sac filled, the liver was rotated downward, giving the impression of ptosis of the liver. In one such case of pericardial effusion noted, as the fluid was withdrawn and the liver came up, the pallor of the lips was removed and redness returned during the aspiration. Reliance could be placed on these two diagnostic signs, but there was no satisfactory explanation as to why pallor of the lips occurred.

Dr. W. H. ROBEY of Boston said he thought that one was aided by any light that could be thrown on pericarditis, either of the serous or fibrinous type. He noted in many of Dr. Stone's plates that the costohepatic angle was not obtuse, and in many cases the fluid was small in amount. Relatively large amounts of fluid did not produce signs of pressure, except at the time when the fluid was first forming and the sac had not had time to accommodate itself to the abnormal pressure. The signs were much more pronounced early than late. Last year Dr. Christian had read a paper in regard to the cases seen at the Brigham hospital, and had spoken of the "Ewing sign", that is consolidation inside of the angle of the left scapula, when the fluid was posterior, so that the heart was driven against the chest wall. The cardiac impulse in these cases did not become less distinct. In one case where the Ewing sign was present, yet the cardiac impulse was distinct, the patient was tapped in the 4th space, to the right of the sternum, and there was a dry tap. It was said that great caution should be used in aspiration, not to puncture the wall of the heart. The speaker said he had gone into the cardiac muscle without harm and knew of but one instance in which puncture produced hemorrhage; indeed a great many patients were relieved by drawing blood from the ventricle, especially when there was cyanosis. In one case of the Ewing sign with fluid, the patient died suddenly with dilated heart. One could have endocarditis, fibrinous pericarditis, perisplenitis, or perihepatitis without fluid. One could not, therefore, rely entirely on Ewing's sign.

Dr. HENRY SEWALL of Denver said that it was important to define all the possibilities. The objection to pericardial effusion was that it prevented the diastolic enlargement of the heart. Three factors entered into this subject: the inherent condition of the heart; the amount of fluid in the pericardium; and the size of the pericardial sac upon which depended the pressure exerted on the surface of the heart. With rapid dilatation of the sac, the pressure was kept low, and under the opposite conditions a few drops of fluid would greatly raise pressure. As to therapeutics, one wondered if some patients would have died if they had been turned over on the face. Posture was important in these cases for relief of pressure, so much so that if a vein should be kinked for 15 seconds, the man could not recover.

Dr. STONE, in closing, said that he had not seen displacement of the liver downward in pericardial effusion. Nearly all his cases were associated with empyema in which fixation of the diaphragm had occurred. In regard to Dr. Christian's paper, one of the plates showed distinct rotation of the heart toward the posterior chest wall and in that case signs of effusion were marked in the back. It was believed that consolidation of the lung or a mediastinitis had caused distortion and rotated the heart. The sign was not probably of great significance except from the standpoint of associated pathology. The speaker said that he had punctured the ventricles of the heart a number of times and he did not know that any particular harm had ensued, but he believed that to carry a needle through a septic, thickened pericardial membrane and introduce it into the blood stream was a very undesirable surgical procedure, and should be avoided if possible. With the use of the *x*-ray, and keeping within the area of dulness, the point to the left of and above the nipple was the most satisfactory one for aspiration. The point in the costal cartilage was rarely available because of the associated empyema.

Effective and Practical Treatment of Malaria to Disinfect Infected Persons and to Prevent Relapse.—Dr. CHARLES C. BASS of New Orleans presented this paper. The object of treatment was not only to give enough quinine to relieve clinical symptoms, but the amount and duration of dosage should be sufficient to disinfect the individual, that is, to destroy every malarial parasite in the blood, and thus prevent the disease from being carried to others. The quinine needed to be given long after the patient thought he was well. Treatment had to be administered in convenient form, preferably in tablets. As the quinine was slowly absorbed and slowly eliminated, one dose daily was found sufficient. It was best given at night when any possibly uncomfortable sequelæ were not noticed. The practice of administering quinine in acid solution was not one to ensure continuance of the remedy by the patients, and doctors who were in the habit of giving it in this nauseous form should try it themselves first, to see what likelihood there was of its being followed. For children the aromatic solution was found most applicable. Not more quinine than was absolutely necessary should be given, first on account of the waste of drug, and secondly because of the tinnitus and urticaria which it often caused. Examination of patients showed that the usual treatment resulted in about 10 per cent. of persons being thoroughly disinfected. One dose of 10 grains of quinine sulphate daily for a period of eight weeks would disinfect more than 90 per cent. of cases of malaria occurring in the country.

Dr. C. W. WILLIAMSON of Chicago said that in his city they did not see many cases of malaria, but when seen it presented interesting problems. Three cases had been seen in the past four years. All in young men, after exposure to cold. The diagnosis was made of lobar pneumonia. None of these patients had been out of Chicago; none had had malaria before. Blood examination revealed the real condition. One patient was treated for 5 months with 30 grains of quinine a day. He had had a recurrence even after that. The temperature in Chicago in February, when these cases were seen, was below zero, and it would be interesting if Dr. Bass could say whether he thought that exposure to this intense cold was enough to account for lowered resistance and the malarial symptoms.

Dr. BASS, in closing, said that he did not think it was well known just what exposure to cold and other causes did to lower resistance and cause relapse. Many people who were infected could go along very well, and yet those people if exposed to sudden chill, would develop an attack of malarial fever. With even temperature, with little difference between noon and night readings, there was not as much malarial relapse as there was in the seasons of spring and fall when there were extremes of temperature. This was only one of the factors influencing vitality. In regard to the cold of Chicago producing lowered resistance and malarial attacks, one could only say that when more was known about immunity processes and the reasons that produce sudden relapses, the question could be answered better.

Errors in the Diagnosis of Chronic Pulmonary Tuberculosis.—Drs. THOMAS MCCRAE and ELMER FUNK of Philadelphia presented this paper which was read by Dr. Funk. Of 1200 cases with a diagnosis of ad-

vanced tuberculous cases, admitted to the General Hospital, 72 were nontuberculous, that is, wrong diagnoses had been made. Among these mistakes could be enumerated 19 cardiorenal cases; 9 of pneumonic sequelæ; 8 bronchiectases; 8 abscesses of the lung; 6 emphysemata and chronic bronchitis 5 neoplasms; 4 syphilis, and the rest miscellaneous cases, such as malnutrition, foreign body, etc. In the acute and chronic nontuberculous lesions the patient had a cold, felt ill, had a persistent cough and signs in the lower lobe. The diagnosis in these cases rested on the presence or absence of organisms and the duration of signs and symptoms. Many atypical pneumonias of long duration were doubtless mistaken for tuberculosis and the necessity of taking repeated sputum examinations was to be emphasized. The cases mentioned of syphilis of the lung were identified by their recovery under specific treatment. Bronchial asthma and anthracosis had been found among the wrong diagnoses. The foreign body cases formed a certain percentage and many of these people had been in tuberculosis sanatoriums. The necessity of careful examination in these cases was apparent. Generally speaking about 6 per cent. of cases had a wrong diagnosis clinically and about 5.2 per cent. were found at autopsy, so that an estimate of these errors could be appreciated.

Dr. Leo Kessel of New York said that it was difficult to realize the readiness with which mistakes were made. So much emphasis had been laid upon the importance of early diagnosis, that one lost sight of the fact that mistakes could occur in advanced cases. Large numbers of cases seen in heart and lung service illustrated the possibility of mistakes. Dr. J. A. Miller had published work on the nontuberculous respiratory infections. These patients were apt to apply for hospital admission between January and March. They felt perfectly well in summer. Often they had spent 1 to 3 years in a sanatorium, and had been discharged with a diagnosis of tuberculosis. Few symptoms were noted. In a severe winter they were usually admitted with a cough, bloody expectoration, and fever. Careful examination of the sputum of these people would reveal pneumococci and streptococci. Physical signs would be found at the base of the lung, with dulness, crepitation, and impairment of breathing on that side. It was very easy to mistake the diagnosis in these cases. Syphilis of the lung sometimes resulted in extensive chest involvement. It was a rare condition. Not more than three cases had been seen in a large service at Bellevue hospital, and the diagnosis should be accepted with a certain degree of scepticism. Some were cardiorenal cases and some had aneurysm and suffered with cough, fever, and bloody expectoration. Mistakes were made by overlooking new growths, primary or secondary, of the lung and pleura. Metastatic growths of the lung had been seen, from carcinoma of the prostate. Careful examination of the sputum must be made, and the *x*-ray was of tremendous assistance.

Dr. J. A. Lichty of Pittsburgh, Pa., said that there was difficulty in differentiating between frank pulmonary tuberculosis and mild bronchiestasis. The mistake was frequently made. The after effects of influenza on the lung were often what one would diagnose as tuberculous if one had not known the history. Kirkman of Philadelphia gave a series of lectures in 1904-5 upon nonbacillary phthisis. It was not until after tuberculosis had been studied that his conclusions were accepted. The same kind of cases were seen after the epidemic of 1889-90.

Dr. F. J. Pottenger of Los Angeles, Cal., said that it was not wise to give the idea that one was diagnosing more cases than were necessary as tuberculosis. Ten times more cases were missed than were wrongly diagnosed. Postinfluenzal cases gave a great deal of trouble. It was difficult to determine whether they were simply postinfluenzal or were tuberculous. Sometimes they were both. Active tuberculosis was easily stirred up. Sometimes influenza involved the apex. In his own cases Dr. Pottenger had seen bronchiectasis and lung abscess diagnosed as tuberculosis. Careful study was needed, as negative sputum did not always mean no tuberculosis. One patient with extensive involvement for five years sometimes had no bacilli in her sputum for weeks. On the other hand, to find the bacilli did not always mean tuberculosis. In chronic pulmonary tuberculosis an abscess would form in the middle of the infiltrated area, but primary pulmonary abscess was a focal infection, not widely distributed. In pulmonary bronchiectasis the condition was in the bronchi, but there were not many rales. With a nontuberculous process one would not get symptoms on auscultation.

Dr. A. G. Shortle of Albuquerque, New Mexico, said that there should be a routine Wassermann made in the handling of these cases. Syphilis of the lung might not be present, but 50 per cent. of cases with actual syphilis present might be overlooked. In 200 routine Wassermanns he had found 10 per cent. positive. The read of the paper mentioned four cases out of 1200; that was a very small percentage. Seven to eight per cent. of cases would no doubt present a positive Wassermann.

Dr. Funk, in closing, said it was difficult to classify patients with a persistent cough. The *x*-ray and the history of previous influenza would help a little. In basal lesion with clear apex one had pretty fair evidence, but not entirely conclusive. Of 134 consecutive autopsies, in not one was there a primary basal lesion which was tuberculous. Dr. Funk added, however, that if the lesions were apical it was not necessarily tuberculosis. It was rare that an advanced tuberculous lesion was closed, but this sometimes occurred.

Third Day—Friday, June 13.

Dr. W. S. Thayer of Baltimore in the Chair.

Symposium on Medicine in the American Expeditionary Forces.—Dr. Thayer said that he felt almost out of place in presiding at a meeting in which the general management had been so very dignified and genial. He did not remember any meeting in which the program was better or which had been so well managed as this one. In regard to the professional service on the other side, Dr. Thayer said that on the entrance of the United States into the war the small compact army groups found themselves confronted with immense problems. The regular army nucleus had to take administrative powers and to place the care of the soldier in the hands of the Medical Reserve Corps. A group of advisors or consultants was formed to advise with the Surgeon General in the practice of medicine and surgery. Drs. Finney and Thayer were told that they would be responsible for the character of surgery and medicine in the A. E. F. Three divisions were formed: the surgical under General Finney; the sanitary corps under Colonel Suyler; the medical division under the speaker. The character and assignment of the medical officers and supervision and standardization of the work fell under these various administrators. Medical emergency teams were formed to assist at the front in the treatment of surgical shock. Dr. Salmon headed the neuropsychiatric division and did valuable work in the neurological hospital of the advanced area in which psychoses and neuroses were treated. Later, during the Argonne offensive, a neurological hospital was established at a base from which the subjects of anxiety neuroses, after resting, were sent back to their units. Col. Dexter of Cleveland had charge of the gas poisoning cases, and Col. Gerald Webb of Colorado Springs of the establishment of tuberculosis centers. Cardiovascular treatment was studied under Dr. Lewis of England, and Col. A. E. Cohn of New York was placed at the head of this work. All this work was necessarily enlarged during the war. Hospitals of 1,000 beds often held, in emergency, 2,000 beds and sometimes as many as 42,000 patients were held at one center. Camp hospitals were established with varying sized contingents. The work being done at the time the armistice came was of a very valuable character. Men were needed with exact training in physical diagnosis, for the consultants' positions. One man who was very much wanted was serving with the Red Cross Hospital. This man went on to front line ambulance work. It was felt strongly that he would have been of value as chief of the medical service, but he preferred to work as a regimental surgeon, living in the trenches, going over the top with his men, and

removing the wounded from the field. On trying to get him back one was met with two statements: that he wasn't willing to come, and that nobody could spare him. He never was removed from the point of greatest danger. He was recommended for every decoration and deserved them all. Dr. Thayer added that having made Dr. Pincoffs thoroughly uncomfortable, he would ask him to speak.

The Division: Evacuation and Ambulance.—Dr. MAURICE C. PINCOFFS of Chicago presented this branch of the subject. He said that medical problems of the division were not of supreme importance to the army. Problems of evacuation overshadowed purely medical questions. During the process of demobilization criticism must be constructive or it would have no results for the future. The organization could be criticized in certain respects. Many duties did not require medical training, and this type of work was assigned to medical officers and took half of their time. This was a waste of medical capacity, and it had a consequence upon the work as a whole and upon the civilian population at home. To the medical duties there was added such work as inspection, instruction, supervision of water supply, and drilling of medical corps men. These duties could be equally well performed by men of sanitary or military training. A military officer could better attend to disciplinary matters and leave the medical officer to do instruction along orthopedic and prophylactic lines. In battle this would be of great value. The usual rush of walking wounded and surgical cases overcrowded the aid post, and the medical officer had to assume the maintenance of order and often to leave serious cases to carry out this issue. At nightfall, when the field had to be carefully hunted over for wounded, this fell to the medical officer, but should have been done by a nonmedical man. The litter bearers had to do difficult and dangerous work, and it fell to the lot of the medical man to see that they were fed and relieved. This could also be undertaken by an army officer. The work of evacuation of wounded, superintendance of ambulance and supply trains, greasing of axles, and inspection of tires could be done without having to waste four years in a medical school. Sanitary inspection could be done by sanitary engineers and thus release thirty-four medical officers for each division. Many intelligent college men were used for driving ambulances, but these men would have made good material for transportation officers. Transportation of medical supplies should be left to army officers. In this way the waste which occurred of at least one-third of the medical capacity could have been avoided. With a view to future war the capacity for effective expansion should be studied. Any attempt to change existing arrangements during the war would have been difficult. The only thing was to see it through, but not to effect reorganization now would be unforgivable. The army and the profession should now apply the lessons learned from experience.

The Corps and the Army.—Dr. GEORGE DRAPER of New York presented this topic. Two distinct obligations lay upon the medical department in the war: administration, and the care of the sick and wounded. Each phase was equally important, and no one man could cover both functions. History was apt to repeat itself in generalities rather than in details. War recurred, but methods changed. By fulfilling the medical obligation to relieve suffering, the numerical strength of the army was maintained. Transportation of supplies, hospitalization, and professional service to the wounded were dealt with by medical men. The actual removing of wounded from the field to hospital was most important from the military standpoint. By the early discovery and removal of wounded men it was possible to reduce the time of waiting by several hours. The Second Division averaged three or four hours better in this respect than the others, and this made a great difference in the morale of the men. The men were sure they would be picked up sooner, and the result was most encouraging. The unusual success of this division was due to the fact that Drs. Pincoffs and Derby went among the stretcher bearers. The hospital itself presented a variety of disturbances. Surgical shock became a medical problem. Cases of gassing, exhaustion, war neuroses, effort syndrome, and malingering made a confused mass of symptomatology. At Bellevue Hospital it was considered necessary to have three experts on diagnosis, but at the triages one often found oculists, nose and throat specialists or the youngest lieutenant in charge of such work. It was realized, however, that to diagnose conditions properly, so that men should be returned to the front as soon as possible, was the work of a skilled internist. The medical problems were as numerous as the surgical ones. Men were called as consultants, but were sent out without due authority, and their reception varied from cooperation to definite antagonism. Supervision of shock and of epidemiology fell to these men, and each worked out treatment in the best way he knew. This was confusing to the division surgeons who worked under them. There was great need of experienced men at the triages, but these should have had authority equal to the responsibility of their work. They should not have had to wander about asking whom they could help. One saw operating tables with glittering instruments, and nobody on them, while outside in the mud were men dying of shock, because it was nobody's work to pick them up. The recovery of the wounded obviously belonged to one set of men. Their treatment to another. Those who knew how to do one thing well should be in a position to do it.

Dr. HOMER F. SWIFT of New York said that he was able to discuss Dr. Draper's paper from his own experience. In the arrangement of the service there should be close cooperation between the chief surgeon and the consultant. The effectiveness of the work of the chief surgeon would depend upon how he would utilize men and whom he would utilize. Obviously in any organization there must be one person responsible for the entire work, and unfortunately in this case it was the chief surgeon. If he used his consultants they became as much part of the organization as did the ambulance men. Although their work and functions might be different, there must be a definite policy. Divisions were moved from one group to another, or from one army to another, and men could not look ahead one month. The function of the army was to lay down policies and the function of the corps to see them carried out. Cooperation should be between the chief surgeon, to the group surgeon, thence to the division surgeon. In the same way the consultant should have the ear of the chief surgeon, and somebody should see that the orders were carried out. It could be done in a teaching or advisory capacity, and the division men should carry it out.

Dr. W. S. THAYER said that when this work was begun in December, 1917, it was in a fluid condition and formed to meet existing conditions. It was a superstructure which did not become fixed. He strongly felt the necessity in the future for the separation of administrative from professional duties, and the recognition that, from the front back, there must be professional supervision. The responsibility was not easy to fix, and this was due to the fact that the whole scheme was in process of evolution. While there were definite ideas being formulated, some of the officers at the front hardly knew of the superstructure.

The Work of the Group Consultant.—Dr. JOSEPH A. CAPPS of Chicago read this paper. The medical consultant did not come into being until late in the summer of 1918. Facilities were arranged between the chiefs of base hospitals of the unit to maintain this liaison between the services. The post of consultant was an experiment. The man had orders to make good. He had to keep in touch with new conditions and advances in diagnosis and treatment. The separation of contagious diseases in the wards and maintenance of proper quarantine were under his care, and the commanding officer received his recommendations. Uniformity of medical service was desirable. Men did not know what was going on in neighboring units because of the exacting demands of the service. Medical societies were then formed which did much to bring the men together. Consultants met at monthly meetings and at special ones in regard to epidemics. Gas treatment was given at the triages. Cases of phosgene and chlorine gas poisoning had passed through the dangerous state before they reached the base hospital. Mustard gas cases were apt to develop secondary infections. Influenza was not a clear-cut disease, and statistics should be interpreted liberally. The mortality was

cut down by lessening the danger of cross-infections. A great opportunity for the consultant in preventive medicine was in the transportation of the wounded from front to rear. The trains were crowded with exhausted men and gassed cases. Attempts were made to separate these cases at the stations, but the rush was too great. Nevertheless, this problem of separating gassed cases from respiratory infections seemed of vital importance. Curtains and masks could have been used to prevent the spread of respiratory infections. In spite of many shortcomings, the work of the A. E. F. did reflect credit on the profession.

The Work of the Group Consultant.—Dr. JOSEPH SAILER of Philadelphia presented this topic. The duties of the consultant were ill defined. Actual authority was slight, and often there was professional jealousy, but, on the whole, there was little difficulty in carrying out the work. This was, of course, largely a matter of personality. During the war the hotels in France were turned into hospitals and the number of patients constantly exceeded the normal capacity, so that they were overcrowded to a serious degree. Patients were placed without reference to diagnosis and no effort was made to prevent cross-infection. There was considerable objection to a pneumonia hospital, but Col. Webb recommended the establishment of one, and this was found to be an advantage as regards both men and surgeons. Influenza was more difficult to handle. Certain wards were set aside. Typhoid fever was rarely seen, but two cases were found at autopsy. One hotel was held for contagious diseases, with separate floors for different diseases. Diphtheria caused considerable anxiety, but any epidemic was checked. Two wounds were infected by diphtheria bacilli, but this was apparently a rare complication. Mumps and measles were rare. The management of diarrhea was found to be largely dietetic. The men were segregated, because, owing to the generosity of their comrades, it was hard to restrict their diet. The care of the throat fell short of what was desired, and better preparation should be made for the future. One fault was the exaltation of the administrative over the clinical work. Men who did not understand clinical work were given too much authority. Adequate encouragement of clinical work in the army would add much to its efficiency. The internist and the surgeon were of the highest importance to the sick soldier.

Dr. H. WOODYATT of Chicago said that it was important that administrative work should be performed by men trained as physicians. Medical officers had to perform administrative duties without the equipment of the nonmedical officers. The medical officer should see that the work is done and also have at his disposal sanitary men to do the administrative details that did not require the services of trained diagnosticians.

Dr. J. HALSEY said that the carrying out of the recommendations of the consultant depended upon his getting the ear of the commanding general, through the chief surgeon of the unit, although many times the chief surgeon of his corps did not have complete cooperation of the general commanding his unit. Often he had to beg for certain improvements that were obviously necessary. The efficiency of the consultant depended upon the way he went about his work. He should have the cooperation of his commanding officer, who could carry out the work with the one above.

Dr. WILLIAM DARRACH of New York said that he could not resist saying a word or two on the question of the consultant. The whole problem was a real one and very necessary to be considered. The problems of the consultant were difficult but they were carried out to a logical conclusion. These results were best shown in the third army after the armistice was signed. In the army of occupation Col. Grissinger had had confidence in his consultant and used his services to the best of his ability and there was hearty cooperation between the administrative and the clinical branches. There were two consultants, medical and surgical, and they had men in charge of supplies and transportation. There were sanitary inspectors and epidemiologists, venereal specialists, psychiatrists, eye, ear, nose and throat men, and urologists. These men in charge of departments had had experience in divisional work and were battalion medical officers of experience at the base. Their education was rounded out. The most serious criticism was that the men did not take time to learn the professional game. One had to take trouble to learn the other man's side. There had to be a co-operation of the clinical problems with the administrative problems. If the armistice had been delayed for another few months the profession would have seen a real union between the two services.

Dr. M. C. PINCOFFS said that in regard to immediate recognition of gassed cases, many were so diagnosed that were not gas cases at all. Many cases were sent back that were gasping nervously because they thought they had been gassed. The army was hampered with gas experts who had training with gas at the rear of the line and who had learned all about the chemistry of the various gases and had the names all pat. A man was sent from the British army to lecture on gas and this set the morale of the officers and men very far back. Every man thought he was gassed at first. Some of these gas experts received an order to investigate personally any reports that such and such a company had been gassed. Such an officer had ordered 100 men of the speaker's command to evacuate because they had slept in a wood that smelt of gas the night before and a number of them had injected sclerotics. Dr. Pincoffs said he intercepted the men at the nearest village and returned them next day to the line. There was no syndrome that called for more knowledge of the psychology of the soldier, and the greatest skill was needed to know whether or not a man had been gassed.

Dr. THAYER said that Col. Grissinger had sent men to the British area to learn the diagnosis and treatment of gas, and the medical gas officers had reached considerable efficiency in the triages in the detection of early gassing. Later the policy of a special gas hospital was adopted. At this hospital there were a considerable number of mild cases. Many of these men were sent back to their divisions without having to pass down the line into the base hospital. Early and effective treatment was of great value.

Later Effects.—Dr. A. E. COHN of New York read this paper. It was difficult to define late effects and when they began. Changes of the eyes, the skin, and the gastrointestinal tract were seen. The cardioneural symptoms known as "irritable heart" were often manifested. Statistics from the A. E. F. were not yet ready. British figures, however, showed that 90 per cent. were returned to full duty in 4 to 6 weeks after gassing; 10 per cent. were sent to England. Convalescence lasted from 6 to 8 weeks, the longest disability lasting 26 weeks. Symptoms of photophobia, effort syndrome, bronchitis, and vomiting were noted; 0.3 per cent. were permanently disabled; 0.7 per cent. died. The majority of the severely gassed returned to full duty. The great danger was injury to the mucous membranes of the respiratory tract with superimposed infection. Aphonia, due to destruction of the mucous membrane was noted, and relaxation of the smooth muscle of the larynx. Sometimes there was psychic disturbance. Effort syndrome often developed in hospital where men got exaggerated ideas of gas effects. They developed anxiety neuroses, shortness of breath, dizziness, headache. It was difficult to say whether this was neurotic or whether gas affected the heart muscle. Post mortem studies were in favor of the neurotic origin of the disease. Many of these symptoms disappeared when the armistice was signed. The nervous disorders in these patients were probably the result of anoxemia. Much relief was obtained by treatment in the oxygen chamber with 40 per cent. + oxygen. Men often thought they had been gassed when they had not, and presented aphonia and photophobia.

Surgeon General IRELAND said that he had heard some very interesting facts in this discussion. The army really recognized now what waste of man power had taken place, and how to keep power at the front line. It was realized that the best work of the medical officer was to keep men from being separated from their fighting units and get them back to the front. Once sent to the rear, it was difficult to get a man back. Men in France accomplished wonders in keeping men near their organizations for a few days' rest. It had been said that professional men had had to do

non-professional work. This was the outgrowth of organization. The problem of transportation became exceedingly large in the war and medical men had had to handle this to a certain extent. In the reorganization of the army which must take place a service board must be given, to allow of the medical officer devoting all his time to the care of the sick and wounded.

Pathology.—Dr. ALWIN M. PAPPENHEIMER of Hartsdale, N. Y., presented this paper. A chemical service and laboratory were established at Chaumont to study material by histological and chemical methods and check up results of new gases used by the Germans. Material from 70 cases was collected. Many men with phosgene gas poisoning died at the front. Concentrated arsene gases caused fatal lesions. The bulk of the cases were caused by mustard gas. The cases were not so clear-cut as in the experimental animals, as the patients were seen when pneumonia was rife and the symptoms were no doubt due to the superimposed infection. The picture of apathy, mental symptoms, and low blood pressure made the French think of adrenal insufficiency in gas poisoning, but though these organs were studied, no conclusion was reached. Cases of phosgene gas intoxication died in 24 hours; of other gases in nine or ten days. Pathological studies showed that repair began to take place in the epithelium and squamous nonciliated cells, and as a result of widespread scar tissue in the bronchi, pneumonia followed.

Dr. J. CRUMBINE said he had studied the effect on the hematopoietic system and had noted the development of a leucopenia. This was due to toxic action on the bone marrow and apparently on the leucocytes. This caused a diminution of the leucocytes in the circulating blood at the time of the greatest mortality of the disease. Attention should be called to the possible relationship of the leucopenia and lowered resistance to the occurrence of superimposed infection.

Trench Fever.—Dr. HOMER F. SWIFT of New York read this paper. The differentiation of this from other diseases which might have previously existed was important. It was unknown where this disease originated, or the way in which lines of infection traveled. Medical officers were ignorant of the condition; it was designated as P. U. O. (pyrexia of undetermined origin). Enlarged spleen, nystagmus, rash, pain, and tenderness were noted. Three types were encountered: (1) The relapsing type, with remissions of 4 to 6 days; (2) a short type, which might be confused with influenza; (3) a prolonged fever. Fever was the most definite sign. The spleen was found to be harder than in typhoid fever and not as large as in malaria. The cases were difficult of diagnosis because of movement of the troops. Twenty thousand cases of P. U. O. were registered. The disease was clearly a louse-borne infection. The virus was very resistant, being able to stand a temperature of 60° C. for half an hour. The urine and saliva of patients were sometimes infected. Long periods of latency of the disease with late relapses were often noted, and it was observed that after delousing of troops the number of cases fell off. As regards the figures of frequency, it was noted that five-sixths of the cases were reported from one-seventh of the troops, and it was supposed that it existed among the other forces, but was not recognized. Disability might be for a period of six weeks, but cases of long duration up to one year were noted. The disease was often followed by the effort syndrome or cardiac symptoms after persistence of the infection. The problem of trench fever dissemination after the war would have to be taken in hand. Many soldiers would be carriers, even after effective delousing measures were carried out.

Influenza.—Dr. WARFIELD T. LONGCOPE of New York made this presentation. The origin of the disease, he said, was still obscure. It appeared in Spain, France, and England in 1918, spread over the British and French armies, and probably the Austrian and German. There were three definite outbreaks: one in May, 1918; the second in September and October, 1918; the third in January and February, 1919. Between these definite waves, intermediate and scattered cases occurred, with respiratory infections. The epidemic of May, 1918, included 36,000 British cases, of mild type and short duration, without complications and with sudden onset; the convalescence was rapid and uneventful. Serious respiratory involvement was not common, although pneumonia was occasionally seen. In August, 1918, respiratory involvement became alarming. It would be interesting to compare figures of mortality, morbidity, and symptomatology of the disease in the A. E. F. as it appeared in camps in this country. The effects of cold and exposure were not entirely clear. Some areas were much more affected than others under similar conditions. Crowded transportation naturally increased the pneumonia. In regard to bacteriology and symptomatology, they were the same in France as here. Meningococci were isolated in some of the cases, and evidently played a part as secondary invaders. In the intermediate stages between the outbreaks respiratory infections were common, often in those who had had influenza. Probably the bacteria which were secondary invaders were widely distributed and had increased in virulence.

Dr. FUSSELL of Philadelphia said that the mortality of uncomplicated influenza was low. In the outbreak of 1889 it was 1 per cent.; probably in this epidemic it was 2 or 3 per cent. The high death rate was due to pneumonic complications. The preponderance of bronchopneumonia, as compared to lobar pneumonia, was high. The rate of kidney involvement was probably about 8 per cent. of all cases.

Dr. E. R. LE COUNT of Philadelphia said that he made the first post mortem in France in April, 1918. The lungs of the patient were full of hemorrhages. The case was clinically diagnosed as poliomyelitis or meningitis. The material from the pleura was studied chemically and histologically. It was not until fall that it was realized what the case really was.

Dr. E. ZUEBLIN of Cincinnati said in regard to trench fever that he would like to know whether, besides cardiac manifestations, any other syndrome had been encountered. Was destroying the lice enough to protect against the disease? Was it clearly known how long the infected patient was a danger to the community?

Dr. H. F. SWIFT said that the disease was not fatal. Cardiac symptoms appeared in probably 50 per cent. of the patients. Effort syndrome was commonly due to trench fever. Other symptoms were leg pains and lumbar pains (often called chronic rheumatism). There was no way as yet to tell how long the patient would remain a possible source of infection. Nor was it known how long it was that the patient infected the lice before the lice infected a human being. As soon as symptoms appeared it would be well to suspect the patient as being capable of infection. As regards infestation, the amount of heat necessary to kill the lice was 56°-60° C., but this was not enough to kill the virus. It took a higher degree of heat for disinfection than for disinfestation.

Nephritis in the Soldier.—Dr. REGINALD FITZ of New York gave this paper. Two types of nephritis were seen: chronic and acute. In 1915 the latter appeared among the British, French, and Austrians. Five per cent. of all cases admitted to the British base hospitals had acute nephritis. Several points were manifest: the acuteness of onset, dizziness, rapidity of development of edema and its rapid disappearance, uremic manifestations. The disease was not confined to any one class, officers as well as men coming down with it. No etiological factor was discovered. There was often coincident bronchitis. The edema was marked over the face and sternum. The subacute nephritis lasted several months. The albuminuria was high at first and gradually fell away in the later stages. Urinary sediment tended to clear up slowly; blood, granular and hyaline casts were noted for a long time. The symptoms were typical of acute nephritis with hypertension. Occasionally epileptoid complications and mild delirium were seen. Cases were unfit for further military duty. Treatment was at first by rest and liquid diet. Efforts were made to avoid the ingestion of proteins and salts, and systematic dietetic regulations were carried out. Few drugs were used and purgation was avoided; if necessary, enemata were administered. No effort was made to lower blood pressure. Occasionally bleeding stopped the convulsions. The diet was gradually made more liberal. The period of observation lasted several months.

Dr. Vil of Camp Dix, N. Y., said that a number of cases had been returned to Camp Dix. The persistence of hematuria with albuminuria was noted. The cases resisted hospital treatment for several weeks. They were discharged with considerable disability.

Dr. E. P. Jocelin of Boston said that he saw a large number of cases under supervision. Dr. Gray at Vichy collected the addresses of all of his patients, with the idea of following them up after their discharge from the army for a five-year period. Dr. Vanderveer was doing the same. Finally no doubt interesting facts would come to light in regard to such cases. In general the harmlessness of the disease at the time of its height was obvious. The cases were found, if one looked for them, at the end of the influenza epidemic. Systematic urine examination was made and cases promptly came to light which otherwise would have been overlooked.

Dr. N. E. Jones of Roanoke, Va., said that the chronic interstitial type was absent.

Dr. Swift of New York said that following the active fighting from July to November, few cases went through the triages. Many cases were described as trench nephritis. Better living conditions were followed by a larger number of cases than were previously seen, but many of the cases did not have influenza infection.

Dr. Fitz, in closing, said that the clinical picture was distinctly acute. The cases often followed tonsilitis. They developed albuminuria and hematuria without retention, which was characteristic of the trench type.

The Treatment of Chest Injuries.—Dr. M. A. Blankenhorn of Orville, O., presented this topic. It was interesting to note the amount of damage done by foreign bodies in the thorax and the indications for treatment. With proper science the surgeon could enter the thorax and remove the foreign body. Warfare and its wounds and surgery were now apt to change with kaleidoscopic rapidity and it would be futile to predict what would happen in future wars. Cases seen in the present war included: (1) Open pneumothorax; in these anatomical repair was followed by immediate relief; the wound was stopped with a plug. (2) Parietal wounds with extensive damage were a source of infection, and opening the chest had been found a safe procedure, with but little shock if a nitrous oxide machine were used to prevent collapse of the lung by pressure. (3) Foreign bodies; machine gun bullets were not so harmful as fragments of shrapnel with torn clothing. Usually there were hemorrhage and shock. Transfusion was harmful in these cases. The foreign body and necrotic tissue were removed and the less done to the lung the better. Gas pressure was used during the operation to prevent collapse of the sound lung. Infection of the pleural sinus was a great danger. The pleura was, however, found to be more resistant to contamination than was supposed. It was essential to prevent accumulation of air and fluid and to maintain the pleura in its natural state and position. Tapping was used to draw off fluid which was not clotted. The cases often made a rapid and uncomplicated recovery. (4) Hemothorax; the infected cases were drained; if free drainage were established, the patient had a chance to recover. At the base hospital an empyema cavity was treated by the Carrel-Dakin method and the patient did well.

Dr. E. Zueblin of Cincinnati said that he would like to ask about the frequency of double pneumothorax, of hydrothorax. and of hydropneumothorax. He was surprised to see in an article by Captain Green that one could tap both pleural cavities and no harm would result. In irrigation of the pleural cavity, what kind of solution was advocated? Double drainage with two cannulas often aided in clearing up the fluid.

Dr. Blankenhorn said he had seen a few cases of double pneumothorax, but never double open pneumothorax, the closed kind was the rule. Double hemothorax was the same. Bullets frequently traversed both chest cavities, producing double hemothorax and double pneumothorax. Results in these cases were often good. As to irrigation, the Carrel-Dakin solution was used to dislodge fibrin from the pleura and from the opening of the wound and thus reach the hemothorax and putrefactive organisms more quickly. The routine plan of the French and British was to give Carrel-Dakin treatment till the bacterial count came down and then to close the wound. Restoration of the membranes would allow expansion of the lung, then on reoperation there was a small empyema to deal with. That was considered a better method than making an effort to expand the collapsed lung. One must avoid obliterating the pleural sinus.

FOOD CONDITIONS AND NUTRITIONAL DISEASES IN EUROPE; WITH SOME REMARKS ON THE ETIOLOGY OF PELLAGRA.*

BY LIEUTENANT COLONEL SEALE HARRIS, M.C., U. S. A.,
BIRMINGHAM, ALABAMA.

SINCE I shall discuss the work on gastroenterology in the United States Army during the World War before one of the sessions of the Section on Gastroenterology and Proctology during the meeting of the American Medical Association, and since practically all of the members of the American Gastroenterologic Association will be present at that time, I shall not take up your time now to dwell upon the accomplishments and the sacrifices of gastro-enterologists to serve their country in the greatest crisis of our history. I would like to say, however, that the patriotism manifested by members of the American Gastro-enterologic Association has not been exceeded by the members of any other specialty in medicine or surgery. Though many of our members are over age, and others belong to the teaching staff medical colleges, whom the Surgeon General declined to commission in the Army because the training of medical students was considered essential war work, the members of this Association never failed when called upon to make any sacrifice for war work.

I would like to mention the service that was rendered by quite a number of men in gastroenterology, but time will not permit my going into a discussion of the many splendid things that were done by individual members of the American Gastroenterological Association. It is enough to say that all of you did your duty, as you saw it, and too much credit or praise cannot be accorded to the men of our specialty for their part in war work.

During ten months of service in Europe, I had the good fortune to visit France, Belgium, England, Italy, Austro-Hungary (Trent, Triest, Istria, Fiume, etc.), and Germany. The relation of food conditions to nutritional diseases in those countries interested me tremendously, and it occurred to me that other gastro-enterologists would like to hear something of the results of my investigations on this subject.

Food and Fighting Efficiency.—In discussing "Food Conditions and Nutritional Diseases in Europe" it may be well to mention, first, that the American armies, both in the United States and in Europe, throughout our participation in the World War, have been the best fed troops in the history of warfare. It is true that our army rations have contained an excess of proteins (meats, beans, etc.), but otherwise the soldiers' diet has been well balanced, with plenty of good wholesome food for everyone.

The selection, purchase, and transportation of food for an army of more than 2,000,000 in a foreign country, 3000 miles from home, and the preparation of this food under conditions in which our troops fought in France, is surely among the great achievements of the war. Napoleon is credited with saying that "an army moves on its stomach," and the fact that the American troops were so well fed may account partly for the efficiency and the eagerness with which they fought, always moving at a rapid pace toward Germany.

I had the privilege several times of eating with our soldiers at the "front," and in various other places in France; and they were always well supplied with food, except on the occasions when sometimes in the midst of battles food had to be carried to them at night. I also had the opportunity of observing the meals that were served the French and British soldiers, on several occasions. They were not so well supplied with food, nor was it so well prepared as for our men.

It is not entirely irrelevant to say that the American troops were the finest looking soldiers in Europe, and the reason that they were such perfect specimens of physical health was partly due to the fact that they were always supplied with good wholesome food. The greatest thrill that I have ever had —and one that I felt many times—was to see our soldiers marching in France and Germany. I saw them marching to the front, returning to rest camp after battles, and in various parades; and it was always with the same thrill and pride that I watched them.

The fact that the Allies had much more food than the German and Austrian troops was a great advantage to us. On one occasion, last October, in Rheims, I saw 4,000 German soldiers the day after they were captured by the Americans and French in the fighting around Grand Pré. They showed unmistakable evidences of being undernourished. Later, in Germany, I was told by a medical officer in the German army that it was a fact that for the last few months of the war, even though the German soldiers were better fed than the civil population, they did not have enough food to keep them in good fighting condition.

Corroborating the statement that the United States Army has been well nourished during the

*Read before the American Gastro-Enterologic Association, Atlantic City, June 9 and 10, 1919.

World War is a recent report of the War Department which shows that American soldiers gained, on an average, 12 pounds during their recent service in the Army. Contrast this with the fact that in the Spanish-American War our soldiers lost on an average 22 pounds each, and the difference is startling. It should be said, however, that the average loss of weight in the Spanish-American War was not all due to lack of the proper food; because nearly 20 per cent. of American soldiers in that war had typhoid fever, and were discharged from service before they had regained their weight. The difference of 32 pounds in the average weight of American soldiers after serving in the Spanish-American War and in the World War is a great tribute to the improvement in the efficiency of the quartermaster's and medical departments of the United States Army.

Food Infection After German Retreats.—The care with which our food was protected from infection also speaks well for American efficiency. During my service in the Surgeon General's Office when in charge of the Section on Gastro-enterology, in the Division of Internal Medicine, I inspected the work in digestive diseases in a number of base hospitals, and had reports from the gastro-enterologists in all of them—and not one case of food poisoning or food infection was reported. I did not learn of any cases of food infection in France, except during the "drives" when sanitary conditions were found to be particularly bad in the territory that had been occupied by the Germans. The Germans after their defeat and retreat in the Chateau Thiery region are said to have left things in a frightful condition.

Colonel Grissinger, in discussing "Feces Disposal and Fly Prevention in a Division,"[1] at the September meeting of the Research Society in Paris, gave a graphic account of the horrible conditions left by the Germans in their retreat. He said that they left horses and men dead and putrefying on the battlefields in the hot sun for days; and they seemingly tried to infect everything that they could not take with them. They polluted the wells and streams, and defecated on the floors, tables, and chairs, and even in bureau drawers, and everywhere they thought they could ruin furniture and houses, so that nothing could be used by the victorious troops of the Allies. Our soldiers said that it was a great deal easier to "clean up" the Germans in fighting than it was to clean up after them when they had been whipped. As a result of the filthy habits of the Germans, flies were swarming everywhere, and it was impossible to keep them away from food.

From various enemy reports which were secured by the Allies, and the visible manifestations of dysentery which the Germans left behind in their retreats, their soldiers must have suffered more from dysentery than did those of the Allied armies. It is surely a fact that until the end of summer wherever our armies chased the Germans, in spite of every precaution that rapidly advancing troops could take, they developed epidemics of dysentery. These epidemics were of the bacillary type, the Flexner-Shiga bacilli being the principal offenders, though often there were mixed infections.

Zinsser,[2] at the September meeting of the Research Society, reported that among the thousands of cases of dysentery among American soldiers, the paratyphoid bacilli had been found in a few cases. He had also observed in the feces of a number of cases a new bacillus closely resembling the typhoid group. Siler[3] at the same meeting said that in a number of cases of dysentery among American soldiers in France the *Entameba histolytica* had been found. There were thousands of cases of nausea, vomiting, and diarrhea, usually ascribed to food infection or to contaminated water, after the Chateau Thiery drive. They were usually mild and subsided after a few days' rest with restricted diet. There were, however, many cases of severe dysentery.

Food Conditions in France in 1918-1919.—Food conditions among the civil population of France in 1918 were serious, though not so bad as I expected to find them. When I arrived there in May it was not possible, at least in hotels, to get milk, butter or other fats, and sugar. Bread, which was heavy and unpalatable, could be obtained, but not in sufficient quantity. Apparently there was plenty of meat, but all the fat was cut off before it was sold, and it was very expensive, so that the poor could not buy it. The delicious French rolls, cakes, pastries, and other delightful gastronomic memories of those who had been to France before the war, were not to be had at any price. France was surely on war rations in 1918.

My personal experience illustrates the food situation in France last year. After having lived for three months in what is considered one of the best pensions (boarding houses) in Paris, I weighed and found that I had lost ten pounds. I mentioned this fact at the table, which seated twenty-five or more, where there were a number of American, French, and Italian officers, and found that all of those who had been in France for some time had lost flesh in amounts ranging from ten to forty pounds. We were getting the nicest antifat diet imaginable, but it was typical of what was served everywhere in France. All our food was nicely prepared and none of us realized that we were not getting enough to eat until we found that we were losing flesh.

The French breakfast ordinarily consists of rolls, butter, and coffee or cocoa; but we had only two thin slices of war bread, no butter, no milk or cream for our coffee or cocoa, and it was sweetened with saccharin. We were, therefore, consuming less than 300 food calories for breakfast.

For luncheon we had plenty of vegetables, potatoes, rice, meats (particularly beef, veal, and fish), and fruit, oranges, figs or grapes. Dinner was the same as luncheon except the addition of a thin soup. We had no milk, butter, sugar, or desserts, except fruits—usually grapes. I estimated that we were getting about 2,000 calories of food a day, one-fourth of which was proteins—not a well-balanced diet, or one on which health and efficiency could be maintained for many months. I, therefore, moved to the Officers' Club (Hotel du Palais), in charge of the American Y. M. C. A., which provided us with everything that the French markets afforded, and in addition, butter, sugar, canned milk, and plenty of bread. I soon regained the flesh that I had lost and felt more like performing the work that I had to do.

Nutritional Diseases in France.—There can be no question but that for two or three years the whole

French population has been undernourished, particularly the poor,and as a result the general death rate, especially among children, has increased considerably. Tuberculosis has increased enormously among the civil population of France. The same is true of the anemias. Scurvy, particularly the infantile variety, which was said to be rare in France prior to the war, is now a frequent condition. Epidemics of Vincent's angina, dysentery, and the infections of childhood are said to have been worse than ever known in France. I could find no one in northern France who had seen pellagra, but I did not visit the southern districts, where it formerly prevailed. It should be mentioned that the American Red Cross had saved thousands of lives and has prevented many more thousands of cases of illness by distributing food and in establishing free clinics all over France.

The shortage of fats, sugar, and wheat products in France lasted up to several months after the signing of the armistice. Conditions were improving when I left France in February, but food was still so expensive that the French complained that they could not buy it. Incidentally, the French blame the Americans for raising the price of food and everything else that is sold in France.

Food Conditions in England.—I was in England in June of last year, and apparently there was a more serious food shortage there than in France, and there is no doubt but that the British suffered greatly because of their inability to get sufficient fats, meats, and sugars. While there was apparently plenty of meat everywhere in France, it could not be obtained, except on cards, and then only in small quantities, in the hotels and cafés in London. Fish, however, was available. I was in England for only a week and my work was such that I had but little opportunity to investigate food conditions and nutritional diseases, but I am convinced that the British suffered more than the French from the shortage of food.

The Italian War Diet.—Food conditions in Italy were worse than in either France or England. I spent three weeks there in January of this year, and from the information that was obtained from Red Cross workers, and from many Italians, I am convinced that there was a very serious shortage of meat and wheat in Italy in 1917 and 1918. Indeed, I was informed that the disaffection in the Italian Army, which resulted in the disastrous retreat in 1917, was largely due to the fact that the Italian soldiers, and the civil population of Italy to a greater extent, were not getting enough food. I was also informed that the American Red Cross had much to do with keeping Italy in the war by furnishing her people with food during the great crisis through which that country passed in 1917.

The meat shortage in Italy was said to have been most serious. Even two months after the signing of the armistice meat could not be had at many of the hotels and it was so expensive that the poor could get but little. The fact that the Italian Government prohibited the manufacture of marcaroni and spaghetti is proof enough of the scarcity of wheat. The only macaroni I saw in Italy was in the American hospital at Vicenza. This hospital, which received wheat from America, had a macaroni machine which was said to have been worked overtime; and partly for this reason the sick and wounded Italian soldiers—the "macaronis" as the American "doughboys" called them—wanted to be treated by the American surgeons in Italy.

Pellagra in Italy.—Since the Italians could not get meat and wheat products, their diet consisted of cornmeal (polenta), rice (risotti), potatoes, and other vegetables. They also had beet sugar. They had no milk and eggs were so scarce and so expensive that only the rich could get them. The Italians, for several years, have lived on a very unbalanced diet, markedly deficient in proteins, excessive in carbohydrates, and the vitamines contained in milk were not obtainable—much the same food conditions that exist among the poor in the rural districts of the South, where pellagra has seemed to be spreading during the past ten years.

In spite of this unbalanced diet pellagra has decreased very markedly in Italy since the war began. All the Italians with whom I discussed the subject said that pellagra has decreased to such an extent in the last twenty years that it is now a rare disease in that country. Just why this decrease has occurred, no one attempted to explain. All observers agreed that tuberculosis, scurvy, and other diseases in which malnutrition is an important factor have increased very greatly since the war began. The general death rate and that from the infectious diseases of childhood have also been excessive, which are accounted for by the low diet which the people of Italy have been forced to live upon.

The doctors in Rome said that there was no pellagra there but that there was plenty of it in northern Italy. At Padua, near Venice, where the headquarters of the Italian Army is located, I was informed that there was no pellagra in that part of the country. At Vicenza, near Verona, the medical officers, largely from New Orleans and Asheville, in the American hospital, through which many thousand sick Italians have passed, said that they had not seen anything that even remotely resembled pellagra, and that they had not heard the disease mentioned by the Italians. After chasing pellagra all over Italy it seemed that it was like the "snakes in Ireland," but I did not learn the name of the particular patron saint that is driving pellagra out of Italy.

I went to the office of the Surgeon General of the Italian Army, hoping to get some statistics on pellagra, but was informed that only a few cases had been reported among the five or six millions of soldiers that had been drafted in Italy. The only information that I could get on pellagra in the Italian Army was the statement that among the eighteen-year-old boys who had been called in the service in 1918 only thirty-four had been rejected because of pellagra.

The vital statistics division of the Italian public health service was also visited, hoping to get some data on the prevalence of pellagra, but the physician in charge said that there were no reliable statistics concerning pellagra in Italy. He said that he was quite sure that pellagra had decreased enormously in the past two decades, but that he had no data to prove it. He promised to send me the statistics on pellagra that could be obtained in his office, but up to this time they have not been received.

Italian Theories of the Etiology of Pellagra.—

The Italian physicians with whom I talked were familiar with Goldberger's theory of an unbalanced or deficient diet being the cause of pellagra, but they do not accept it. They seem very much divided as to the etiological factors which might account for pellagra. Ceni's view that pellagra is due to a toxin elaborated by an aspergillum which grows on maize that has not been dried thoroughly is believed in by some; and there are still those who believe in Lombroso's theory of its being due to some unknown factor in maize.

Sambon's belief that the *Simulium reptans* is the cause of pellagra is not accepted by many Italians. Alessandrini has made investigations which convince him that a deficiency of silicon in the diet is the cause of pellagra. Most of the Italians, however, from the best information that I could gather, think that the cause of pellagra is yet to be discovered.

Conditions in Austria and Hungary.—Food conditions in southern Austria were much worse than in Italy, but in Trent and Trieste I could find no pellagra. In Goryza, around which the Italians and Austrians fought for two years, the inhabitants said that they had not had meat for months, and they showed many evidences of undernourishment. The death rate, they said, had increased enormously from tuberculosis and children's diseases, but there was no pellagra. In southern Hungary, at Pola and Fiume in Istria, much the same conditions were found. They had an excess of carbohydrates, particularly beet sugar, and a deficiency of proteins, and the physicians there said they had no pellagra.

Starving Germany.—There has been such a difference of opinion regarding food conditions in Germany that it may be well to go a little more into detail in describing the investigations which I made there in February of this year. I made a number of inquiries regarding food conditions and found that the rations for an adult for the week ending February 1 consisted of: 100 grams of barley, 100 grams of potato flour; 5 lb. of potatoes (four potatoes average a pound, with half of them rotten, but the people have to accept what is allotted to them by the government); 2,000 grams of bread; 150 grams of meat on Saturday only (this is equal to about one-quarter of a pound and not more than enough for one meal). I asked how often they ate meat, and they all said "once a week." They are allowed only 50 grams of fats (margarine) in ten days. Eggs cannot be obtained at any price and there is practically no milk. Adults are allowed half a pound of beet-sugar per month and children are given half this amount. Children from one to three years are allowed half a litre (1 pint) of milk per day, if there is any, but apparently there is very little—none in many places.

I purposely did not discuss food conditions with any of the office-holders or politicians, but talked to men, women, and children on the streets, in stores, shops, and hotels. I also talked to physicians. From ten years old upward the German population seemed to know the exact number of grams that they were to get of all kinds of food, and with few exceptions all those with whom I talked showed evidence of lack of nourishment and complained that they were not getting enough to eat.

I went into a number of stores which had quite an imposing display in the windows, but found inside that many of the shelves had nothing on them or contained empty boxes from which the contents had been sold. Some of the meat shops and grocery stores make displays of food, but it cannot be sold except on government cards, and at such nigh prices that none but the rich can buy it. With few exceptions the girls and women with whom I talked in the various stores showed marked evidences of anemia, and said they had lost weight in amounts ranging from 10 to 45 pounds. Two young girls with whom I talked had gained weight since the war, but they were at a growing age when their height and weight would naturally increase. All classes of people, particularly the women and children, lacked energy and vitality. They seemed very different from the German people whom I knew in 1906.

Undernourished Children.—A number of children trudging along to school through the snow, wearing paper sandals in cloth shoes with wooden soles, presented a pitiable spectacle. I asked them what they had had to eat that day and for the past week. All of them replied: "Soup, potatoes, and a little bread." The soup is made of barley or potato flour, and often contains vegetables but no meat. Not one of thirty or more children remembered when they had had milk. The Germans seem to have more vegetables than anything else, but many vegetables are now being eaten that never were before. For instance, the sugar beet, which is extremely coarse, is said to be used quite generally; and a tough tuber, the name of which I have forgotten—a cross between a potato and a turnip—was also being eaten.

The bread that is issued to the Germans, by card, is heavy, black, gritty, and tasteless. It is made of flour sold by the government and no one seemed to know just what is its exact composition. It is thought to be barley, potatoes, and beet root. None of this flour is sold except to bakers and they can sell only a limited amount of bread to each person, and then only upon receipt of a ticket for the daily or weekly supply.

Bread and Peace.—I questioned a number of people as to the reason why the war ended so suddenly, and one very intelligent young man in a stationery shop expressed the opinion of the majority with whom I discussed the subject when he said that the people were starving; that they had to have bread; that there was a great deal of dissatisfaction; that the papers had kept the fact regarding the war situation from the German people, and they did not know how badly their army had been beaten; that the papers had talked of victory until September and October, when the Germans made their peace drive. This young man and others said that the terms of the armistice were considered very hard, yet they were willing to do anything to end the war and get food. The German people then saw that their only hope of getting peace—which meant to them *bread*—was to overthrow the Kaiser's regime. The Kaiser was informed of the dissatisfaction of his people, and realizing that his life was in danger he abdicated and fled to Holland. It was the angry cry of his hungry people that reached the ears of the German monarch, as well as the fact that he knew that his armies were

beaten and were becoming demoralized, which caused the greatest despot in history to give up his "divine" right to the throne.

Hunger was also the moving power that vacated the thrones in some of the lesser kingdoms of the German Empire. The King of Bavaria before the war affected agriculture, and had a large stock farm to which he gave his personal attention. When food began to be very scarce in 1917 the king sold milk to his subjects at a higher rate than had been charged by the dairymen. The disaffected laborers used this as propaganda in prejudicing the people against their king and the epithet "profiteering milk-farmer" was given him. I was told that this incident helped to make him so unpopular that he was forced to abdicate.

Tuberculosis and other Diseases.—As we know, persons who are in a state of low vitality fall an easy victim to tuberculosis, pneumonia, and many other diseases. Tuberculosis and pneumonia are, therefore, increasing enormously among the Germans. I could not get statistics proving this, but doctors and people from all classes told me so.

One physician, a dermatologist, said that there had been a very great increase in skin diseases, particularly urticaria (nettle-rash) and other trophic disturbances. An apparently new skin disease has appeared in the form of nodules all over the body, often with considerable pigmentation of the skin of the face, which is said to be very difficult to cure. These skin troubles are undoubtedly caused by the lack of proper nourishment, and also the scarcity of soap which made it impossible for the Germans to keep as clean as they should—although they never were fond of bathing. I asked him if he had seen any skin lesions resembling pellagra which is prevalent in the southern States, and which has been claimed to be due to an unbalanced died not very unlike that which the Germans have been getting; but he said that so far as he knew, there had been no cases of pellagra in Germany, that he had seen no skin lesions that resembled those of that disease.

The severe types of anemia among the women and children are said to occur frequently, and some estimate that more than a million people in Germany have died because of lack of proper food, not from starvation alone, but from infectious diseases of which the predisposing factor is malnutrition.

The surgeons of Germany say that malignant diseases of the intestines are very much more frequent among young people than was ever known before. It is thought that the coarse bread which is given out by the Government is the cause of this. I was unable to obtain any statistical data as to this increase in intestinal diseases.

The Increase in Suicides Among Germans.—The suicide rate in Germany has always been high, but since the Armistice it is said to have increased enormously, particularly among the professional classes. The cause of this increase in suicide rate is thought to be the lack of nourishment and the despair of thinking men and women in Germany who see no future for themselves or for their country.

Quite a number of prominent physicians in various lines of work are said to have committed suicide. Among them was Dr. Adolph Schmidt, whom most of you know, and whom I think all of us have considered to be one of the greatest authorities in the world on intestinal diseases. I regarded him as one of the most courteous gentlemen and one of the ablest physicians whom I have ever known. I shall never cease to appreciate his kindness to me. While working in Berlin, in 1906, I had been informed of Dr. Schmidt's wonderful work in intestinal test diets. En route from Berlin to Vienna, I spent several days in Dresden and Dr. Schmidt, without fee or hope of reward, gave up much of his time to show me the work that he was doing. It was, therefore, with genuine sorrow that I heard of the tragic end of this great man, even though he was a Colonel in the Medical Department of the German Army. I have wondered, too, what has become of many others of the great physicians in Germany and Austria, at whose feet we sat in our studies abroad. No doubt many of them are living, but alas! we can never again go to them for the knowledge and inspiration that has been responsible to a very great extent for developing the science and practice of gastro-enterology.

Compensations to the Germans from a Low Diet.—Even starvation has its compensations and German physicians say that since overeating has not been possible since 1916, there has been a decrease in stomach diseases, but that when a gastric disorder does arise, it is very difficult to relieve, because the proper diet is lacking. I was also informed that the low diet has helped a great many people who were accustomed to overeating before the war; and that liver diseases, chronic nephritis, Bright's disease, and other chronic ailments which affect men and women over 50 years of age, have decreased considerably. Diabetes, a disease which in many cases is thought to be due to overeating, and in which the best treatment is starvation, is said to have disappeared from Germany. I asked a physician about gout, a disease formerly much dreaded by the Germans. He laughed, and replied "we don't have gout any more."

I heard considerable complaint about the beer which the Germans are getting. They said that there is no "substance" in it. It was described as "colored, brown water, a mysterious stuff that people can drink any amount of and never get crazy." One man, however, said that the German people were enormously better off because they cannot get their beer.

The Germans have had no coffee for three years. They have prepared substitutes of parched acorns, or burnt barley and chicory, which are not unlike genuine coffee in taste and appearance, but lack the "kick" of coffee because they are free from the stimulant, caffeine, which is the active principle of the coffee bean. Caffeine is really a powerful drug, and, therefore, excessive coffee-drinking, such as was the German habit before the war, is harmful. Since coffee has practically no food value except from the sugar and cream with which it is usually taken, the Germans are fortunate to be freed from the caffeine habit. They have tea which also contains caffeine, but few Germans seem to have the tea habit.

Food Conditions in Belgium.—I spent only two days in Belgium in February of this year, having followed the route taken by the Germans in 1914,

going from Cologne to Aachen (Aix la Chapelle) then to Liège, Louvain, and Brussels. I was traveling in an automobile and made stops at only three places, Louvain, Brussels, and one village, the name of which I have forgotten. The difference in the appearance of the people across the line from Germany into Belgium was quite marked. I did not stop at Liège, but saw children on the streets eating big white "buns" that brought up memories of my boyhood days. The Belgians appeared to be well nourished, and in Brussels, while food was expensive, though not much more so than in New York, plenty of cakes, pies, meats, eggs, and apparently all kinds of food, were obtainable. Belgian rations as allowed by the Government, are bountiful when compared to that of the Germans. Apparently the United States Food commission has been able to supply Belgium with food and clothing throughout the war.

I did not have the opportunity of talking to anyone in Belgium except hotel and shop keepers, but apparently the Belgians, in so far as food is concerned have fared better than the natives of any other country in Europe. I could get no information of value regarding nutritional diseases, but was informed by laymen that tuberculosis has increased during the war, and that the death rate among children has also greatly increased.

Goldberger's Theories.—I desire it distinctly understood that I do not pretend to present a thorough study of food conditions in the European countries that I visited. It would take months to make anything like an accurate investigation of food conditions and nutritional diseases in any one country. Statistics on a large scale in any country are not to be had, and they would be thoroughly unreliable, if there were any, because of the war conditions in Europe. I also recognize the fact that the epidemiological study of a disease is not the best way to determine its etiology; but it is surely suggestive that with much the same food conditions in a number of European countries that exist among the poor in the rural districts of the South, which Goldberger, with many well known medical men concurring in his opinion, has announced is the cause of pellagra in the Southern States, there seems to be very little pellagra—none in Germany where food conditions are worse.

I am sorry that I have never been able to accept without reservation the Goldberger theory of the etiology of pellagra,[6] because it is the best argument that I know of for diversified farming, and for the general improvement of the living conditions of the rural population of the South. Indeed, I feel that in promulgating his theory Dr. Goldberger and the United States Public Health Service have performed valuable work for the South. If Dr. Goldberger's experiments had been carried out in Canada, or in Maine, where there is no pellagra, his results would have been more convincing, but they were carried out in States in which the disease was quite prevalent, and under conditions which seem to me did not preclude the possibility of infection playing a part.[6]

The High Protein Diet in the Treatment of Pellagra.—Dr. Goldberger has also made a contribution of great therapeutic value in stressing the importance of the heavy protein diet in the prevention and treatment of pellagra, though I must disagree with him in his stated opinion that medicines have little value in its therapy. I recently attended a meeting of the Alabama State Medical Association and there discussed the subject of pellagra. Some of my former students in the medical department of the University of Alabama, in which I had the chair of medicine for seven years, reminded me that years before Goldberger's theories were announced, I taught them that pellagra from the clinical viewpoint simulates tuberculosis in many respects, that in both diseases undernourishment is one of the great predisposing factors, and that the most essential agencies in their treatment, are rest and a diet rich in proteins, particularly meats, eggs, and milk. They also remembered that as far back as 1907 the pellagra patients in my service at the Mobile City Hospital were treated much as our tuberculous cases were managed, except that the latter were kept on the porches night and day, while the pellagrins remained indoors out of the sunlight.

In an address before the Chicago Medical Society, in June, 1917,[7] prior to the publication of Goldberger's work, I urged practically the same treatment that Goldberger advises, plus the use of medicines as indicated.

I do not claim priority in advising forced feeding in pellagra, because in the Italian literature on the disease, there are a number of references to practically the Goldberger diet, before the disease became prevalent in the South; and many physicians throughout the South have for years used the high protein diet in pellagra.

Doubtful if Unbalanced Diet is the Cause of Pellagra.—Please understand that I do not even yet say that pellagra is not entirely a nutritional disease, due to an unbalanced and a deficient diet. What I mean to say is that the gigantic experiments which the war forced on the peoples of the various countries of Europe were not unlike those which Dr. Goldberger carried out on a small scale, the results of which have not yet been confirmed by others; and yet in some of those countries, apparently there is no pellagra. Even in Italy, where pellagra was almost a scourge a few years ago, the disease has decreased during the war. It seems to me that the inference of there being possibly some other etiological factor than the unbalanced diet as the cause of pellagra, is justified.

I have no convictions as to the etiology of pellagra, but somehow from the course and symptoms of the disease it seems to me possible that it may be due to an infection taken into the gastrointestinal tract from some source. Several thoughts have suggested themselves to me as possible lines of investigations in studying the etiology of pellagra and I will briefly mention them.

Suggestions for Investigations.—The similarity of pellagra and syphilis has been noted since the former was first described. The fact that the use of salvarsan and other arsenical preparations, mercury, and other drugs that have proved helpful in luetic therapy, have also been reported as successful in treating pellagra, is also suggestive. Syphilis is due to a spirochete which was discovered with the use of the dark field microscope. Recently a leptospira was proved to be the etiological factor in infectious jaundice, and a few weeks ago Noguchi,

who is working under Gorgas with the International Yellow Fever Commission in trying to eradicate yellow fever from the world, using the dark field microscope, discovered a leptospira which apparently is the cause of yellow fever.[8] It, therefore, has occurred to me that perhaps pellagra may be due to an organism which may be discovered by studying the blood, tissues, and excretions of pellagrins, with the dark field microscope. The only work of that kind that I know of was carried out by Francis in the Marine Hospital, but his experiments were made on monkeys, who may not be susceptible to pellagra. The investigations of Francis, in making the effort to transmit pellagra to monkeys were very thorough, and should be studied by anyone who undertakes any research work pertaining to the etiology of pellagra.[9]

The day before I left Paris, on Feb. 14, Maj. Gen. Sir John Rose Bradford and Captain Wilson, of the British Medical Service, were in my office, and told me of their investigation of a number of diseases which have been thought to be caused by the filterable virus group of organisms. Using the Noguchi method they discovered an organism which they believe to be the cause of acute infective polyneuritis. Working along the same lines they isolated organisms from the blood in trench fever, influenza, trench nephritis, mumps, measles, and typhus fever. These organisms will all pass through the Berkefeld filter but they present certain cultural characteristics which are distinct and definite in a number of experiments. Investigations of the blood in pellagra following the methods of Bradford and Wilson, on the assumption that it might be due to a filterable virus, may give positive results.

While pellagra is prevalent in the South more than in other sections of the country, cases have been reported in almost every State in the Union. I am quite sure that there are many mild cases, that in their symptoms simulate gastrointestinal intoxications, or infections, in which there are no skin lesions, that get well without the diagnosis having been made. I am also convinced that many cases of chronic diarrhea in all sections of the country are really mild cases of pellagra. It, therefore, is a disease in which gastroenterologists are particularly interested, and when we have cases we should make whatever investigations we can regarding a disease, the etiology of which, many of us believe, is yet to be discovered.

RESULTS OF DUODENAL ALIMENTATION IN PEPTIC ULCERS.*

BY MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO THE LENOX HILL HOSPITAL, NEW YORK.

IT is just nine years since I had the pleasure of reporting to you on duodenal alimentation. While this mode of treatment is applicable to a variety of conditions, its main field is peptic ulcer. It was in this disease that I first employed it. A number of later papers, likewise, refer to the same condition.

Numerous clinicians here and abroad have administered duodenal alimentation in gastric and duodenal ulcerations with benefit. Among these I mention S. Basch, A. F. Chace, R. F. Chase, H. Fischer, J. A. Friedenwald, M. Gross, I. W. Held, W. V. Hayes, J. C. Johnson, A. A. Jones, Clemens Jones, J. A. Lichty, George L. Laporte, Paul Lazarus, Willy Meyer, C. J. MacGuire, William Gerry Morgan, L. Montané, J. A. McCafferty, H. A. Rafsky, Charles G. Stockton, F. Pages, N. de Rosas, L. Stieglitz, Franklin White, J. G. Wells, J. R. Verbrycke, and many others.

It appeared to me of interest to discuss to-day my experience with regard to the results of duodenal alimentation in peptic ulcers.

Peptic ulcers may be divided into: (1) Uncomplicated cases of moderate duration; (2) uncomplicated cases of very long duration; (3) cases complicated by recurrent hemorrhages; (4) cases complicated by obstruction of the pylorus; (5) cases complicated by perigastric adhesions or perigastritis.

All uncomplicated cases (Groups 1 and 2, are amenable to medical treatment, especially to duodenal alimentation. Group 3 should be given a trial by duodenal alimentation. If hemorrhage returns pretty soon after this mode of treatment an interval operation (gastroenterostomy, sometimes, with pyloric occlusion) should be performed. Groups 4 and 5 usually require surgical measures. However, if the stenosis of the pylorus has not reached a high degree, medical treatment can first be tried, and if necessary be followed by stretching of the pylorus through the internal route. In perigastritis the rest period during duodenal alimentation may bring sufficient relief to forestall an operation. The same applies especially to old people or greatly weakened individuals, who could not well stand the hardships of an operation.

Groups 3 and 5, and 4 when the pyloric stenosis is still permeable to the duodenal tube, may when they are in a weakened condition first advantageously be subjected to duodenal alimentation, in order to be brought into a more fit condition for a future operation.

The results of duodenal alimentation in peptic ulcer will depend to a great extent first upon the

*Read before the American Gastroenterologic Association, June 9, 1919, at Atlantic City, N. J.

proper selection of cases and upon a correct diagnosis, second upon a conscientious and detailed handling of this mode of treatment.

Careful observation of the patient, especially in a hospital with systematic examinations for a few days, will usually suffice to make a well-balanced diagnosis. The details of duodenal alimentation can be easily acquired after a short period of study and practice, so that every practitioner could carry it out.

In order to study the results of duodenal alimentation in peptic ulcer I select my material among my private patients of the last nine years. Most of these I could follow for quite a while after treatment, some of them almost up to the present time. To be sure there are some among them in whom the definite result is unknown to me. Selecting, however, those I do know as a basis, the others will probably show approximately similar results, so that the statistics of my material will not be far from the truth.

All in all 315 cases of peptic ulcer were treated by duodenal alimentation. Among these there were 247 with definite localization of the ulcer, as follows:

Localization of the Ulcer in 247 Patients.

	Cardia (35-42).	Lesser Curvature (43-53).	Pylorus (54-55).	Duodenum (Below 55).
Males	10	43	36	65
Females	14	38	19	22

The immediate results were satisfactory in all, excepting four. That means subjectively the patients felt better, could stand more food and a greater variety without suffering, usually could follow their vocations a few weeks after treatment, and a gain in weight varying from 10 to 20 pounds. The string test, as I have observed in a former paper, does not always become negative in the usual two weeks' duodenal alimentation given the patient. In about half the cases the string test remains positive at first, to disappear some weeks later on. In others it remains positive even a longer time after treatment.

It would be perfectly legitimate in these cases to try and extend the period of rest accorded the stomach for a longer period of time. The patients, however, notwithstanding the positive string test, are usually feeling so well that I did not consider it right to subject them to worry and treatment. It is different in cases with manifest complaints. Here another period of duodenal alimentation should be given right away without question.

In looking over the entire list of 315 patients I find 31 which require comment. I give them in a table.

Among these, four had the alimentation without benefit; eight required operation soon after the period of duodenal feeding; four for pyloric obstruction, three for recurrent hemorrhages, and one for perigastric adhesions. Four had to be operated upon later on (*i.e.* 1 to 5 years subsequent to the duodenal alimentation treatment), three of these for pyloric stenosis, and one for recurrent hemorrhages. In 15 there was a recurrence of ulcer symptoms 2 to 5 years after the first duodenal alimentation treatment, necessitating a new period of feeding with benefit to the patient.

I.—Table of Cases of Peptic Ulcer from the 315 Treated by Duodenal Alimentation, in which Imperfect Results have been Obtained (1910-1918)

Name.	Date.	Location of Ulcer.	Remarks.
Miss Lisa S.	10-7-10	Lesser curvature	Recurrence about 1917.
H. T.	10-27-10	Pylorus	Recurrence about 1916.
Richard S.	1-6-11	Duodenum	Recurrence about 1916.
Odie S.	1-6-11	Duodenum	Recurrence 1912 (9-13-12).
A. D. S.	2-16-12	Duodenum	Recurring hemorrhage; operation.
Miss C. G.	11-24-12	Duodenum	Improved; not cured. Recurrence, 9-16-14
H. P. R.	4-25-12	Lesser curvature	Operation four years later.
E. C. M.	4-6-12	Lesser curvature	Recurring hemorrhages six months later; operation.
W. J. Mc.	5-28-12	Duodenum Pyloric stenosis	Duodenal alimentation previous to operation 5-24-12.
F. F. C.	9-19-12	Pylorus	Recurrence 2-19-16.
M. P. D., Jr.	1-12-13	Lesser curvature	Recurrence.
Mr. G.	4-12-13	Pylorus	Two years later hemorrhage; operation.
L. R.	1-4-14	Duodenum	Recurrence 1916.
S. S.	2-16-14		Postoperative dyspepsia; no benefit.
Dr. S. H.	4-5-14	Pylorus	Hemorrhage pretty soon after duodena alimentation; operation.
Miss M. G.	5-3-14	Lesser curvature	Recurrence 1917.
Miss H. P.	9-13-14		Not improved.
Dr. J. E. C.	1-15-15	Duodenum	Recurrence 9-11-18.
Dr. J. P.	4-14-15	Duodenum	Recurrence 12-9-18.
John D.	4-30-15	Cardia	Not much improved.
Miss F.	10-13-15		Required operation later.
M. A.	6-16-16	Duodenum	Not improved.
Mrs. E. R.	8-31-16	Lesser curvature	Recurrence two years later.
Mr. L.	11-25-16	Duodenum	Operation later for pyloric stenosis.
F. J. N.	3-17	Pylorus Stenosis of pylorus	Improved; later hemorrhage; therefore operation.
Jacob C.	3-17	Pylorus	Required operation
A. B. H.	4-15-17	Pylorus	Recurrence, 10-20-17.
Mr. S.	5-19-17	Duodenum	Recurrence, operation.
Mr. S.	1-18-18	Prepyloric ulcer	Required operation on account of perigastric adhesions.
Mrs. P.	2-20-18	Duodenum	Hemorrhage; operation.
Dr. S.	4-18	Duodenum	Required operation.

There were no deaths encountered during the duodenal alimentation. The procedure of duodenal alimentation is certainly not connected with any risks to life.

To be sure there are a great many patients among the 315, whose results are not known to me any more, for they cover a period of nine years.

I thought it might be of interest to look over the results of more recent years, as they are better known to me. I, therefore, take 1915, 1916, and 1917 as examples.

II.—Table of Cases, Treated by Duodenal Alimentation During 1915-1917 Specifying the Imperfect Results.

Year.	Number Treated.	Name.	Location of Ulcer.	Remarks.
1915	47	John D.	Duodenum	Not improved.
		Dr. C.	Duodenum	Relapse in 1918; duodenal alimentation with benefit.
		Dr. P.	Pylorus	Relapse in 1918; duodenal alimentation with relief.
		Mr. P.	Duodenum	Carconoma vent. in 1917.
		Miss F.	Duodenum	Operation later.
1916	39	Mrs. R.	Lesser curvature	Relapse in 1918.
		Mrs. L.	Duodenum	Later required operation for pyloric obstruction.
1917	46	J. C.	Pylorus	Operation for pyloric stenosis pretty soon after duodenal alimentation.
		Mr. N.	Pyloric stenosis	Operation for pyloric stenosis and hemorrhage 2-3 months after treatment.
		Mr. S.	Prepyloric ulcer	Operation for pyloric stenosis 18 months after duodenal alimentation.

In 1915, 47 patients were treated with duodenal alimentation. The results were good, excepting one not improved, one patient with duodenal ulcer and great benefit from treatment (gained 30 pounds in weight) had developed cancer of the lesser curvature 2 years later, from which he died subsequently. One patient required operation for pyloric stenosis. Two required another course of treatment three years later (1918).

In 1916, 39 patients with peptic ulcers were treated by duodenal alimentation. One required operation for pyloric obstruction, another one had a return of ulcer symptoms in 1918.

In 1917, 46 ulcer patients were fed by the duodenum. Three cases required operations for pyloric obstructions. One (J. C.) pretty soon after the alimentation period; another (N.) about three months later; the third 18 months later.

As can be seen at a glance from the above figures the results of duodenal alimentation in peptic ulcers are very favorable. Not taking the late recurrences of ulcer symptoms after two years into consideration the good results would be 95 per cent. Including later recurrences and necessary operations after a two-year period of benefit as failures we would still have recoveries in 90 per cent. of those treated.

If one looks at the special varieties of peptic ulcers with regard to the results of treatment by duodenal alimentation one finds that the imperfect cases are principally encountered in complicated ulcers of long standing and in pyloric and duodenal ulcers with or without recurring hemorrhages. Ulcers of the cardia and lesser curvature give the greatest percentage of cures.

It may be of interest to mention that we applied duodenal alimentation in six cases of abundant recurrent gastric hemorrhages of the severest type, immediately after this event and have achieved perfect cures. They are described in the subjoined table.

III.—Table of Cases of Abundant and Repeated Gastric Hemorrhages, in which Duodenal Alimentation was Administered During or Immediately After the Hemorrhage.

Name.	Date.	Remarks.
Mrs. McQ.	10-4-11	Frequent profuse hemorrhages, constant vomiting, had lost 50 pounds. Treated by duodenal alimentation, gained 60 pounds; remained well ever since.
Mrs. M. K.	10-14	Had lost two-thirds of her blood; recovered after duodenal alimentation.
L. S.	2-15	A patient with duodenal ulcer, and extensive hemorrhage; tube introduced after the bleeding had stopped.
Miss A. de P.	11-16	Had 3-4 extensive hemorrhages in three days, with syncope. Tube introduced during the bleeding period with marked benefit.
Mr. O.	4-19-18	Had several recurrent hemorrhages in one year; in the last hemorrhage he had lost more than half of his blood. Tube applied during the hemorrhage with benefit.
H. P.	4-21-18	Duodenal tube failed to enter the duodenum in 48 hours. Another tube with bead attachment was introduced and passed the pylorus in 18 hours.

Inasmuch as the results will more or less depend upon the handling of the cases it will not be superfluous to give a short outline of the entire plan of the treatment.

The diagnosis of peptic ulcer having been made and the possibility of malignancy having been excluded with great probability, the patency of the pylorus is then ascertained (retention meal of rice or rice and raisins and the duodenal bucket string test). The pylorus not being stenosed (or not strictured to a great extent) the duodenal tube is then introduced and feeding by the tube begun as soon as the latter has reached the duodenum. The period of duodenal feeding is ordinarily two weeks, but can be extended for a longer time, whenever this appears appropriate. During the tube feeding period the patient receives daily 8 meals in two-hour intervals, consisting of milk (7 ounces), one egg, and one to two tablespoonfuls of lactose; besides one pint to a quart of saline twice daily, likewise through the tube. As a medication we usually give subnitrate of bismuth gr. xxx, in conjunction with calcined magnesia gr. ii-v t.i.d., in a wineglassful of water by the mouth. A mouth wash should be frequently applied, and the bowels should be made to move once daily either by medication or by enemas. For nervousness Tr. of valerian or a bromide can be employed and it is best given in the feeding through the tube, and for pains codein or atropine administered in the same manner. Patient is ordinarily kept in bed during the first week of the tube feeding; the second week he is up gradually more and more every day. After the two weeks of tube feeding are completed, the tube is withdrawn and nourishment given by mouth, at first principally liquids, but very soon semi-solids, and in about three days also light solid foods. At first patient is fed every two hours, but as soon as he is on a liberal diet three ordinary meals and two small meals in between are instituted. The above-mentioned bismuth medication is continued for a month or two longer and then gradually discontinued.

In recommending duodenal alimentation for the treatment of peptic ulcers I like to lay emphasis on two important points this method enables us to carry out; namely, rest of the affected organ and adequate nutrition. Moreover, these two most important principles for facilitating a cure can by this method be extended over long periods of time without injury to the system.

20 East Sixty-third Street.

HAYFEVER IN CHILDREN.

By WILLIAM SCHEPPEGRELL, A.M., M.D.,

NEW ORLEANS.

PRESIDENT, AMERICAN HAYFEVER PREVENTION ASSOCIATION; EX-PRESIDENT AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY; CHIEF OF HAYFEVER CLINIC, CHARITY HOSPITAL.

Hayfever is relatively common in children, but the reason that this is not more generally known is that these attacks are usually mistaken for "colds." In view of this, parents should be warned, when the symptoms suggest hayfever, that the child is not exposed to infection from hayfever weeds.

The importance of this is illustrated by the following case: A child of six years had suffered for three weeks with a persistent "cold," complicated by asthmatic attacks at night. The attending physician had given a prescription and advised an abundance of fresh air. With this in view, the mother carried the child every day to a suburban park so as to have the "purest" air. Unfortunately however, the park adjoined a large area of the giant ragweed in a fully-developed state of pollination As the child inhaled the pollen-laden air several hours each day, and the diagnostic test showed marked sensitization to the ragweed, the persistence of the symptoms and the nocturnal asthma could easily be explained.

In our Series C and D of 707 cases, the records show that five per cent. of the hayfever cases developed before the age of 10 years, and 24 per cent. before the age of 20 years.

Sensitization Due to Direct Inhalation of Wild Flowers.—The initial sensitization to hayfever pollens, in children, is frequently due to the direct

inhalation of certain wild flowers. Common among these is the daisy fleabane, *Erigeron strigosus*. While this is not strictly a hayfever plant, as it is fertilized by insects, it produces an abundance of noxious pollen, which will develop hayfever if applied directly to the nostrils. It somewhat resembles the common daisy and is therefore frequently collected by children.

The daisy fleabane is a singularly common weed which grows from 1 to 2 feet in height. The light green leaves are linear and toothless, or nearly so, the lower one being broad at the tip. The little daisy-like flowers are one-half inch in width, and with a large green yellow disk; occasionally the white rays are lilac-tinged and sometimes they are extremely short or altogether absent. They are common in neglected fields and on roadsides.

The pollen of the fleabane is so active that one application of the flower to the nostril may produce an attack of hayfever lasting three or four days. In one case, in which this was inhaled in order to test the reaction, severe symptoms of hayfever developed in a few minutes, and the constitutional symptoms in an hour. The effects lasted four days, the local effect being limited to the left nostril, to which the pollen was applied. This case resembled a "cold" so perfectly that, had the origin not been known, it would undoubtdely have been so considered.

Another common flower, which is not in the list of hayfever weeds because it is not wind-pollinated, but which may cause hayfever in children by direct inhalation, is the common dandelion, *Leontodon taraxacum*. This was naturalized as a weed from Europe, but is now common in fields and waste places generally. Children are attracted by the light yellow flowers, which are frequently applied to the nostrils. As the pollen is quite noxious, it causes hayfever, which is usually mistaken for a "cold" and which, in children, it greatly resembles.

There are many other wild flowers,[1] such as the field daisy, *chrysanthemum*, Black-eye Susan, *rudbekia*, and others, most of which belong to the *Compositæ* family, which, while also harmless in hayfever from a general standpoint, may develop a sensitization in children from direct application to the nostrils.

These flowers are insect-pollinated, and, as the pollen is not found in the air as in the case of wind-pollinated plants, they do not infect the atmosphere for hayfever subjects.[2] When the flower is applied directly to the nostrils, however, and the pollen inhaled in this way, it may develop an anaphylaxis resulting in a sensitization to other hayfever pollens of the same group. As the ragweeds, the principal cause of hayfever in the United States, also belong to the *Compositæ* group, this sensitization may result in a persistent fall hayfever.

A low relative immunity to hayfever pollens is undoubtedly inherited, as shown by the fact that 37 per cent. of hayfever sufferers have relatives of the first degree who suffered from hayfever. This predisposition, however, may remain indefinitely without developing hayfever, as demonstrated by our clinical records, which show that 76 per cent. of hayfever cases do not develop hayfever until the age of 20 to 30, 57 per cent. until 30 to 40, and 27 per cent. above this age.[3]

The development of the initial attack is due either to a lowered resistance as, for instance, from a depressing illness, or, which is the usual case, from increased exposure. If this results in an attack of hayfever, it is followed by an anaphylaxis to atmospheric pollens, which previously failed to develop an attack.

The direct application of certain flowers to the nostrils of children, therefore, should not be allowed, especially in families in which the development of hayfever in some of the members indicates an hereditary predisposition to hayfever.

Adenoids and Tonsils in Hayfever.—Any condition which impairs the normal respiratory passages in children lowers their resistance and makes them more susceptible to hayfever. Prominent among these are the "adenoids," which interfere with normal nasal breathing both directly, by obstructing the posterior nasal passages, and also by causing congestion of the nasal mucous membrane.

Enlarged tonsils, which are usually associated with adenoids, also tend to make children more susceptible to hayfever. The correction of these defects are indicated not only for the hayfever but also for the effects on the respiratory passages generally and the ears.

Asthma in Children.—As in adults, asthma is sometimes the predominant symptom of hayfever in children. In many of these cases the initial nasal symptoms attract little attention in connection with the more serious asthma, and, in some cases these may even be entirely absent. Whenever the asthma is marked during the usual hayfever seasons, the reaction to pollen is probable. Even when this is not the case, in view of the fact that hayfever sometimes assumes the perennial form, the little patient should be given the intradermal test with the pollen extract. Five units of the pollen extract to be tested are injected into the skin, and, if this is followed by a reaction, the immunizing treatment is indicated. The percentage of cures and improvements in these differs but little from the results in the uncomplicated form of hayfever.

Hygienic Measures.—Fresh air and exercise is essential in the treatment of hayfever in children, but weed-infested localities should be avoided.

The diet should be carefully regulated, indigestible food being especially avoided. Foods rich in proteins should be reduced during the hayfever season. In cases complicated with asthma, the diet should be carefully watched and the principal meal be given near the middle of the day.

Treatment.—The treatment of hayfever in children does not differ essentially from that in adults.[4] The diagnostic test is made by injecting into the skin five units of the pollen extract representing the pollen to which the patient is exposed, as, for instance, timothy pollen extract for the *Gramineæ* group, and ragweed extract for the *Ambrosiaceæ* group.[5] The reaction from the injection determines the nature and degree of the patient's sensitization and forms the basis of the immunizing treatment.

The dosage of the injection in children is based on the usual ratio for their age. In a child of 10 to 12 years, for instance, the initial prophylactic dose is 10 units, which is increased by 5 units for each dose, and which is given biweekly until 40 to

50 units per dose is injected. The maximum doses are continued until the usual hayfever season commences, when they are reduced to 20 units.

In acute attacks, in which there is evidence of a catarrhal complication, the autogenous, or, when this is not available, the mixed catarrhal vaccine,[6] is substituted for the pollen extracts, the proportional doses for the age of the child being also observed. When the acute symptoms subsides, the immunizing treatment with the pollen extracts is resumed.

The result of the treatment of these cases has been very encouraging, less than 15 per cent. failing to be followed by a seasonal cure or marked improvement. Cases complicated with asthma appeared to be benefited equally with the uncomplicated form.

THE LITTLE SIGNS OF THYROID DISTURBANCE.*

By JOSHUA H. LEINER, M.D.

NEW YORK

ATTENDING NEUROLOGIST, PHILANTHROPIN HOSPITAL; ASSOCIATE ATTENDING NEUROLOGIST, CENTRAL AND NEUROLOGICAL HOSPITAL, BLACKWELLS ISLAND; CHIEF NEUROLOGICAL DEPARTMENT, LEBANON HOSPITAL, O. P. D.; FIRST ASSISTANT NEUROLOGICAL CLINIC, MT. SINAI HOSPITAL.

THE practice of medicine, so far as the chronic ailments of the human body are concerned, will reach its greatest efficiency when they will no longer have to be treated. If one should become visionary concerning the future of medical science (not art) I can conceive of a series of diagnostic clinics where the abnormal physiology of the human system will be detected in its incipiency; when the gross pathology of disease will be a rarity, just as rare as a case of smallpox is today in a civilized community. It will be by the detection of "little signs" and not by the manifestation of full blown symptoms and the gross lesions that are apparent today.

In the domain of endocrinology even greater emphasis in this direction can be made. The internal secretions control every function of the body—which in a more analytic sense is either catabolic or anabolic in nature. Every organ and every tissue has its internal secretion which either acts for its own existence or for the welfare of the organism as a whole. The thyroid gland is one of the latter variety. I am not considering in this paper the symptoms of myxedematous patients, cachexia strumipriva, or the cases of pronounced hyperthyroidism—it is the "little signs" that are to be looked after; *i.e.* when the thyroid secretion deviates from the normal either way, producing a functual pathology and upsetting the endocrine confederacy. This may be brought about by pregnancy, infectious disease, etc. It can be said axiomatically that the function of the thyroid gland in the body in the widest sense has to do with metabolism. I cannot illustrate the hypofunction of this organ in a more practical manner than by citing a case and then analyzing the "little signs."

Child, H. M., six years old, was brought to me by her mother, who stated that for the past four months she was very nervous, irritable, and had lost her appetite for all foods; she tired easily, seemed sleepy most of the time, and suffered from constipation. Two months previously the child suffered from a severe attack of tonsillitis. This child showed a pasty complexion, her gaze was listless, and she stood with a débutante slouch—as if she had no spinal column. Her tongue was furred, her throat was congested, and her abdomen was distended with gas. Her viscera were normal, her general nervous system was also normal. She had a temperature of 98° per rectum and a pulse of 70 per minute. This case illustrates the "little signs" of hypothyroidism very strikingly. This is not an uncommon type of case that is brought to the physician and the usual thing given is a tonic. Under small doses of thyroid extract a marked change was wrought in this child.

The "little signs" here were the sudden loss of appetite, asthenia, constipation with flatulence, drowsiness, subnormal temperature, and slow pulse. As mentioned previously, one would ordinarily be inclined to prescribe a cathartic and a tonic, but if these "little signs" are taken collectively, it spells one thing, and that is "hypothyroidism."

Persistent constipation in infancy and childhood, after everything else is checked up as a cause, will be found to yield to small doses of thyroid. Marhe produced an intestinal fistula in dogs and fed them with thyroid gland. The intestinal secretions were greatly increased, and undoubtedly the neuromuscular centers of the intestinal tract produced a more powerful peristalsis. This would explain the benefit thyroid therapy produces in constipation. Sir Arbuthnot Lane's theory that constipation produces by means of autointoxication a hypothyroid state is now considered to be a process in the reverse order, *i.e.* that constipation is due to a hypofunction of the thyroid, due most probably to a thickened intestinal wall just as we find the thickened mucinoid subcutaneous tissue in myxedematous states.

A subnormal temperature and slow pulse always indicate a low grade metabolism, and the thyroid stimulates the metabolic processes through its catabolic action. This fact can be better appreciated when we bear in mind the rise of temperature and rapid pulse in the reverse condition, that is, in Basedow's disease. The asthenia is best explained on a pluriglandular basis. We know that the thyroid is synergistic to the adrenals, and when we have a hypofunction of the thyroid the adrenal secretion is diminished, leading to a hypofunction of the sympathetic system with a consequent muscular weakness, which is in turn partly due to a lack of catabolism of glycogen in the striated muscular system. The languor and sleepiness are best explained by Her-

*Read before the Lebanon Hospital Alumni Society, May 6, 1919.

toghe, who assumes that the thyroid is one of the great detoxicating organs of the body, and when we have a hypothyroid condition the metabolic débris or metabolites are not burned up, resulting in the dulling of the higher neurons that make for alertness, initiative, etc. Of course, one must also bear in mind the adrenals in this connection. These individuals, by the way, awake in the morning with a feeling of fatigue rather than being refreshed after a night's sleep. This has been, of course, always considered a characteristic symptom of neurasthenia, which I will leave for another paper. Let me now quote a case from the records of the Neurological Department of Mt. Sinai Hospital. This is a case of spontaneous adult hypothyroidism, the etiology of which is due either to repeated pregnancies or to various infectious diseases.

Mrs. A. B., forty-two years of age, complained of neuralgic pains in the back, paresthesias, a tendency to sleepiness during the day, chilliness and fatigue upon the slightest exertion. Her menses were always scant and have been slowly subsiding for the past two years. Upon examination she shows a pasty complexion, acne over face, tendency to puffiness over back of hands. There is thinning of the outer third of the eyebrows, pulse 60; blood pressure, systolic 112, diastolic 78. Teeth are fair, tongue is coated and there are tremors of her tongue and lips.

This case shows us that this woman went along for years exhibiting the insidious "little signs" of hypothyroidism without detection, and has now entered what Cobb calls a case of submyxedema. Take her sexual organs, she states she did not have a menstrual flow as other women did but simply stained, which I am aware is due to a polyglandular cause, at the bottom of which lies the thyroid, which in turn affects the *corpus luteum*. These cases often come to us complaining of various neuralgias and paresthesias as this case does, and is best explained by the lack of prompt expulsion of deleterious neuroproducts and the sluggish circulation leading to lymph stasis in the neurons. It has been shown that when there is a hypersecretion of the thyroid there is an increased calcium output found in the urine and the reverse is true when there is a hypofunction of the thyroid. There is found here a storing up of calcium in the tissues producing atheroma (Cobb found marked atheroma of the aorta) and a consequent arteriosclerotic process in the blood-vessel walls. In fact, Horsley believes that senility is due to a slight degree of hypothyroidism. The changes in the face, the falling out of hair, the dryness of the skin, the production of adipose tissue, the diminution in the function of the nervous system of the sensorial, intellectual, and genital spheres, all these symptoms are found in advanced old age; in addition we find nutritional exchanges diminished, the pulse is slow, the temperature is subnormal, and there is the sensation of coldness.

Thus, of the two above mentioned cases, the first of rather acute onset following an acute infection and the second a chronic progressive case which has now reached the stage of submyxedema which for years manifested the undiscernible "little signs" of hypothyroidism. One can go on relating case after case in which are shown these small insufficiencies of the thyroid, but in general we can sum up by calling attention to the following, which should prove of practical value in our every day practise: A subnormal temperature, slow pulse, a history of gradual alopecia, nutritional disturbances such as constipation of a chronic variety, lack of appetite, especially in children who prefer sweets to any other food. A history of cold hands and feet or chilblains in a patient should always put us on our guard; a lack of initiative, being easily fatigued, and a tendency to drowsiness during the day are very significant. Enuresis in the child as well as an unexplainable increase in weight in older people will often yield to thyroid therapy.

Let us now turn to the opposite state—the "little signs" of hyperthyroidism. Here a great deal of prophylaxis can be accomplished. As in the small hypothyroid conditions, so in the small hyperfunction of the gland there is nothing classical in the presenting symptoms. These do not stand out by any means. It depends solely upon the keenness of the examiner to pick them out amongst a multitude of symptoms that are purely subjective and often irrelevant; one must become, as Cobb would state, a medical detective. Questioning will sometimes yield corroborative evidence and then objectively one will run across the "little signs" that will clinch the diagnosis of a fruste type of a thyrotoxicosis. These cases in fact come more often to our office to consult us than one can imagine. Following the present pandemic of influenza, there have been found a great number of cases of post-influenzal hyperthyroidism, which I have seen at the clinics and in my private practice.

As an illustration of one of these cases, a woman of sixty following an influenza which she contracted several months previously, complained of headaches, cardiac palpitation, insomnia, nervousness, paresthesia, such as burning sensations after meals in the abdomen and in the extremities; her temperature was 99.50, pulse 110 per minute; in a reclining position the blood pressure was 155 systolic and 95 diastolic. Further physical examination revealed no abnormality whatsoever.

Here the "little signs" were the rapid pulse, tremor of the digits, nervousness, cardiac palpitation, and insomnia.

Another case, Mrs. R., suffered from a pluriglandular involvement, but the outstanding feature was a hyperthyroidism following a severe influenza pneumonia. She came to my office about eight weeks after her illness and complained of the following: Asthenia, hyperchlorhydria, extreme nervousness, hot flushes which required either rushing out into the street for relief or the flinging open of a window. She also had a scanty menstruation. Upon examination no exophthalmia nor tachycardia was present; she showed, however, a slight tremor of the digits. The thyroid gland was not enlarged.

Here again no cardinal symptoms were present, but the "little signs" pointed to an overacting thyroid. One can go on quoting case after case showing these slight upheavals.

The above-mentioned cases were types with mild group symptoms. Most often you will not get them in this fashion, you will only get one or two "little signs," but with these as a basis try and observe your patient with a mental vision and see where his or her symptom-complex belongs. A woman will complain of periods of scanty flow and periods of normal menstruation, a muscular fatigue, and examination will show slight tremor of the fingers; this should put you on your guard. On the other hand, the patient will state that he or she has sud-

denly increased in weight without an obvious reason. Upon examination you will find that they show a greater amount of fatty deposit in the supraclavicular region and in the hypochondrium there is a rough and dry skin and often small patches of eczema are present. If you inquire further a history is elicited of hair falling out, and if so they may perhaps show the sign first called attention to by Leopold Levi and Baron De Rothschild, *i.e.* a scarcity of hair of the eyebrow and a marked diminution of its outer third. Another point I wish to mention, that in the same individual one can find both hyper- and hypothyroid symptoms; this at first would seem to be impossible, but such is the case. I have personally seen two cases where some of the cardinal symptoms of hyperthyroidism were present alongside those showing a hypofunction of the gland. This is a striking occurrence in connection with the pituitary gland, as pointed out by Cushing. A year ago I showed a case before the Neurological Section of the Academy which illustrated this point very well. Dr. Walter Timme has shown that there are types of individuals whose internal secretory glands are upset and at different stages manifest different symptoms, often seemingly contradictory, but understandable if analyzed. This is the syndrome of thymus, pituitary, and adrenals. Every time a gland shows pathological hyperfunctions it will pass through various stages and burn itself out and will eventually stop functioning entirely. In other words, a Basedow will eventually become a case of myxedema. One can therefore observe a patient showing exophthalmia, Von Graefe sign, tremor, together with putting on weight, dullness, and apathy; whereas previously he or she was thin, full of excessive energy, etc.: this shows the transitory phase.

In the treatment of endocrine disturbances one must bear in mind the fact that there is a glandular confederacy and the disturbance of one gland upsets this entire chain. The symptoms therefore are often complex and require considerable analysis. In order to interpret the different symptom-complexes correctly, a knowledge of their physiology is unquestionably necessary.

In closing I am desirous of impressing the fact that for every case manifesting pronounced thyroid disturbances there are at least a half hundred that show only the "little signs," and it is these individuals that go from one doctor's office to another seeking relief. It is only necessary to keep our eyes open, and the more we treat these cases the further away we will drift from prescribing bromides, iron, quinine, strychnine, etc., which nevertheless are often necessary in these conditions.

1186 Boston Road.

PROPHYLAXIS OF THE SEQUELÆ OF INFLUENZA.*

By THOMAS J. TUDOR, M.D.

KEOKEE, VA.

THE recent pandemic of influenza, with an estimated mortality in the United States alone of 500,000 souls, killing five times as many of our people while it lasted as died from all other causes, including the world war, aroused our profession, and we are now trying to digest and assimilate some of the lessons and to correlate our observations. We would naturally gladly do this for the benefit of our successors, who will be called upon to handle the next great pandemic, thirty, forty, or probably fifty years hence; but from the experiences of the past we believe that we, too, will need for our own use every bit of information available.

The third wave of the disease is now subsiding in England, and the probability is that we will have another, with more or less extensive recurrences for the next year or so—possibly for four or five years. Unfortunately, we do not yet know whether the ordinary influenza, or la grippe, which is usually endemic in this country every winter, is identical with this pandemic, but most of us believe that it is not. We have not even recognized and demonstrated any definite germ as the cause of these pandemics, Pfieffer's bacillus, which has held that distinction since the masterly paper of that author in 1892, having failed to meet the critical tests and studies of many of our most learned students of the subject within the past few months.

It is not my purpose to attempt to add anything to the voluminous literature on the subject of the treatment of influenza, which most of us regard as almost wholly symptomatic, but there are a few things which I believe of vital importance as regards the sequelæ, and the first is to keep the patient absolutely in bed from the appearance of the initial symptom until one week after the subsidence of the fever. Some have used the fever thermometer for the early detection of influenza, even among those around and at their work, and one feeling badly with any of the symptoms of the disease during its prevalence should be given the benefit of the doubt and put to bed promptly.

These patients should be kept warm, with an abundance of fresh air in the room but no draft directly on them; no depressing drugs should be given, and I believe that the wide and indiscriminate use of acetylsalicylic acid, often in large doses frequently repeated, has done a great deal of harm; and, while elimination should be kept active, drastic purges from heavy doses of calomel have seemed to serve no good purpose.

In my opinion, these patients should be fed more liberally than has been the custom. The gastrointestinal types, of course, will not retain much food, and for them a diet applicable to that complication is demanded, but most of the others can and will eat, and why should they not? We have learned that cold, fatigue, and hunger are the three great predisposing causes of pneumonia, the most dreaded and frequent sequel of influenza. We can usually keep these patients warm, but toxemia and restlessness produce marked fatigue, and we can avoid hunger by a careful study and ordering a diet which they can digest. I believe that there is a big field in the scientific rational feeding of the sick. So many of our rules and customs in that line have been handed down from author to author. If a typhoid fever patient, with ulcers in his intestines, can with safety and

*Read at a meeting of the Wise Medical Society, Norton, Va., May 28, 1919.

benefit eat a semi-solid diet, why should not these influenza patients? I fed mine, and many a time have seen the sordes, coated furred tongue, bad taste, loathing of food—all aggravated by a liquid diet—clear up as if by magic when the orders were given for them to eat; if they do not want food, let them eat anyway, actually forcing food at first if necessary.

Another thing: Many keen observers believe that the beneficent effect of alcohol in these cases is largely psychic; and if there is anything that encourages the influenza patient more than to let him eat and let him see that he can not only take food but enjoy it, and that his appetite is still with him, I do not know what it is. Some historian of the future will drop a tear of sympathy when he writes the chapter telling of our long devotion to the sickening broths and other devitalized foods. Of course, I realize that there are conditions and diseases when we must fall back on them, but influenza not of the gastrointestinal type is not one of them.

These patients should be kept in a quiet well kept room, as the disease is hard on the nervous system, and for some weeks after they get around they should be shielded as much as possible from excitement, worry, grief, etc. All degrees of mental aberrations are observed from mild hypochondriasis up to melancholia, but most of these under rest and quiet and appropriate treatment will gradually clear up.

It seems illogical to talk of an antitoxin or prophylactic vaccine for a disease of unknown etiology. The wide use of these in this pandemic has been experimental, though it does seem that some of those intended to build up the resisting powers against a possible pneumonia have been of value if the pneumonia developed, and harmless if it did not.

The use of blood plasma from convalescent or cured patients when injected into those desperately ill has seemed to have been attended with good results; and I made a limited trial of the use of convalescent and cured mothers for breast nursing of babies having influenza-pneumonia, and all of these recovered, though some of them were so ill that death seemed certain; I have faith in the antitoxic power of such milk, though my observations have been too limited to prove anything. It has been easy to get mothers to nurse babies other than their own, when the possible curative effect of the milk was explained, and they have taken great pride in the cures.

The use of mildly antiseptic sprays is of value probably as a mechanical cleansing agent, as any known antiseptic, strong enough to have any appreciable or lasting effect in the nose or throat, would so damage these tissues as to predispose to rather than prevent further infection. However, these, as well as throat gargles, if used hot, may be made very soothing and agreeable to the patient.

So much for the care of the patient during the attack. A great deal can be done following the subsidence of the disease to prevent sequelæ. When the patient gets up, he should begin to get around very gradually and cautiously, taking care not to get wet or cold, and he should lie down promptly when he becomes dizzy or tired, and especially during this convalescence should a good nutritious abundant diet, of pleasing variety and rich in vitamines, be supplied; and if the appetite flags a good bitter tonic should be administered, and if there is anemia to any appreciable degree iron should be given.

There will be a great many cases of empyema, chronic bronchitis, quiescent or arrested cases of tuberculosis to light up, and some of them will be new cases. Then there are the cases of nephritis, both acute and chronic, and the various forms of heart troubles, and the so-called rheumatisms which are coming to us. We can watch our clientèle closely and often detect these conditions in their incipiency and thus prevent a great deal of trouble. The pneumonias, associated with or following influenza, require particularly close watching. In hospital wards or homes, the ill of any form of pneumonia should be screened from the other sick, and if two must sleep in the same bed or close together head to foot sleeping should be insisted upon. Whenever there is a pneumonia of the streptococcic type, no other sick one should be allowed in the room, and every precaution should be taken to prevent the spread of this disease that would be taken with a case of scarlet fever. We must develop a wholesome respect for this form of pneumonia and for its infectious and contagious character. Regular typhoid precautions should be taken with the sputum and dishes of all pneumonia patients. For months after attacks of influenza, patients should avoid exposure to infection from those with pneumonia, or other contagious disease, as they certainly bear them badly.

Pregnant women having influenza should go to bed at the very first symptom, or better still avoid exposure to the disease, as these women fare badly. They should be unusually quiet in bed and every effort should be made to control the cough, and if labor, premature or at term, comes on, if possible, delivery should be effected without internal digital examination, and also without the administration of general anesthesia. They should be kept in bed a little longer and watched more closely than in the case of an ordinary confinement, as a great many of them will develop pneumonia, and those that have no complications will be very weak and in poor condition for their later deliveries and periods of infant nursing.

During and following the pandemic elective operations should be postponed until there is a return of the old-time strength and vitality. This applies to the wholesale removal of tonsils—good, bad, and indifferent—often upon the advice of a district nurse, illy fitted for the important function of passing final sentence upon this part of our anatomy for which we are beginning to have some respect as the light of a new day begins to dawn in throat surgery. None of us would plead for the retention of a hopelessly diseased tonsil, but unless the disease within it is extensive and menacing the health of the host, I would wait for the restoration of the normal recuperative powers before advising a tonsillectomy; for if there is a focus of pyogenic infection present, the operation

will open up some new avenues for systemic infection, which in normal health would mean a reaction of a day or so; or there might be considerable hemorrhage, and the blood of the influenza patient even after convalescence is not in good shape for reacting from hemorrhage.

I urge all my influenza patients to get an abundance of sleep during and following convalescence and to spend nine or ten hours in bed every night and also have an afternoon nap when possible. Did you ever notice the prolonged sleep that so frequently follows the favorable turning point in a critical disease, as the crisis in pneumonia? It is Nature's way.

In conclusion, let us take a whole hearted interest in these folks that have had influenza. They need our advice, sympathy, and leadership. It is our opportunity to be of real service. The patent medicine people have sized up the situation and from every daily newspaper glaring advertisements skilfully arranged and lavishly and effectively illustrated catch the eye of the man who has had influenza and has never felt well since, and if he has just come from the office of the family doctor, who has felt his pulse, sounded his chest, and looked at his tongue and told him there is nothing the matter but that he has had the "flu," he is ready to reach out for what is promised by these vendors, and the fact that they are not actuated by the altruistic spirit of his doctor will not occur to him.

These patients should be encouraged, and when they come complaining of frequent or continuous headaches, blank or confused mental states, everlasting fatigue of body and mind, a general good-for-nothing feeling, and a firm conviction that they will never be quite strong and well again, if a painstaking exhaustive examination fails to reveal anything wrong, do not dismiss them but put them on a good tonic and have them report back at regular intervals, and have your personality dominate theirs and sympathetically lead them out and onto the road to health again. I am not arguing for us to play upon their fears; far from it, but this peculiar mental state, when there is no bodily disease basis for it (and which one of us can always say positively that there is not some basis even when we cannot find it?), needs treatment, and if we do not supply it it will be found elsewhere.

Medicolegal Notes.

Cross-Examination of Expert Witnesses.—In an action for malpractice, in which it appeared, although the word "unskilfulness" appeared in the petition, that the action was one for negligent treatment and not for want of skill, on cross-examination of physicians called on behalf of the defendant, the following was permitted over the defendant's objection and exception: "Q. Now, doctor, I want you to tell this jury if you ever treated a patient that was left in that condition by similar injury (having reference to the condition of the plaintiff's ankle). A. If I ever did, I don't remember. I don't say that I haven't. I don't remember if I did." The objection made was that it is not proper cross-examination, in that it puts the witness in such a situation that the natural inclination would be to answer similarly to the answer given here. The defendant, on appeal from a judgment for the plaintiff, in his brief put the matter thus: "Naturally, a physician confronted with such a question would answer in the negative. It would simply be his opinion upon a particular case if he ever had one such, and his opinion could not be expected to convict himself of error."

It was held that this was improper cross-examination and prejudicial. Aside from the force of the situation tending to elicit a negative or non-committal answer, the plaintiff would be establishing that the defendant was negligent by proving what some other physician had or had not done. The court recognized that there is a wide latitude given in the cross-examination of witnesses who have testified in the nature of experts; but it is said in I Wigmore on Evidence, § 878: "Cross-examination is no universal solvent for reducing everything to admissibility." If a physician under such circumstances should answer in the affirmative, then a defendant, situated as in the case at bar, would be entitled to have the physician explain. He could go into all the details of the collateral case, and show all the circumstances such as that the physician being cross-examined was prohibited from doing differently by the patient, or prove any other fact tending to show that the condition of the "patient left in that condition" by the witness was not on account of the negligence of the attending physician. Such a course would lead far afield from the issues, and into matters wholly irrelevant and far beyond the scope of legitimate inquiry. Such cross-examination cannot be said to be harmless and excused on that ground.—Summers v. Tapley (Mo.), 208 S. W. 266.

Medical Opinion Evidence as to Effect of Drugs.—In a prosecution for violation of the federal Food and Drug Act for misbranding an interstate shipment of drugs, as a part of the government's case some well-qualified physicians were called as witnesses and asked if a drug composed according to the formula used by the defendant in preparing the article would, in their opinions, be effective for the treatment of the diseases for which the defendant's labels and statements claimed it was effective treatment, and after answering that it would not be effective, they testified that there was no difference of opinion among medical men on that subject. Objections were made to this testimony, and it was urged that it called for the opinions of the witnesses, for a conclusion that only the jury could properly make, and that no conviction could be based on such matters of opinion. The testimony that there was a general agreement of medical opinion as to the therapeutic effect of such a preparation, and what that general medical opinion was, was held properly admitted to show the falsity of the statements made by the defendant. The testimony of the physicians as to their individual opinions as to the efficacy of the preparation would have been properly rejected if there had been disclosed a difference of medical opinion on the subject, as a conviction could not properly rest upon a claim of fraudulent statements, when they were based upon mere matters of opinion on such debatable subjects. But a mere concurrence of such witness' opinions with the uniform course of medical opinion was not open to that objection.—253 Fed. 696.

Constructions of Harrison Act.—The Circuit Court of Appeals for the Seventh Circuit holds that the provision of section 2 of the Harrison Narcotic Act, after providing that specified narcotic drugs shall be sold on written order forms obtained from the Internal Revenue Department, that "it shall be unlawful for any person to obtain by means of said order forms any of the aforesaid drugs for any purpose other than the use, sale or distribution thereof by him in the conduct of a lawful business in said drugs or in the legitimate practice of his profession" is unconstitutional, as not within the taxing power of Congress, which includes no right to make any specific use of a tax-paid article unlawful (the rest of the section being held constitutional). It is also held that Rev. St. §3236, providing that, whenever more than one pursuit or occupation subject to internal revenue tax are carried on in the same place by the same person, the tax shall be paid for each, requires a separate registration under the Harrison Act by a physician who dispenses and is also a dealer in narcotic drugs, and payment of a separate tax for each; and this is also required by the Internal Revenue regulations.—Blunt v. United States, 255 Fed. 332.

Medical and Surgical Lessons of the War.

VENEREAL PROBLEMS OF THE WAR.

By VICTOR COX PEDERSEN, A.M., M.D., F.A.C.S.,

NEW YORK.

MAJOR, MEDICAL OFFICERS RESERVE CORPS, UNITED STATES ARMY; MEMBER OF THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES, OF THE AMERICAN UROLOGICAL ASSOCIATION, AND OF THE COMMITTEE ON VENEREAL DISEASES OF THE ADVISORY COUNCIL OF THE DEPARTMENT OF HEALTH OF NEW YORK CITY; VISITING UROLOGIST TO ST. MARK'S HOSPITAL; RECENTLY MAJOR, MEDICAL CORPS, UNITED STATES ARMY.

(*Concluded from page* 65.)

THE education of women and girls of immoral tendencies was found to be very important because of peculiar viewpoints. The glamor of the uniform and the foolish idealization of it led many girls astray by their own choice. Many girls, who had never sold themselves to civilians, regarded themselves as doing their duty through intercourse with soldiers and sailors. Adverse surroundings in camp cities, high cost of living, absence from home, improper, insufficient food, underpay, absence of recreation, and such factors were found to be potent in downfalls.

Lectures to women were inaugurated by the War Work Council of the Young Women's Christian Association through its Social Morality Committee and Bureau of Lecturers. The program was made straight Social Hygiene presentation of venereal diseases and women's obligations to the Government accordingly. Between 4,000 and 5,000 lectures were given to students in grade, high, and normal schools, colleges and universities; business women in factories, stores, and offices, and women and girls in mass meetings and clubs. Educational films were used, especially "How Life Begins" and "The End of the Road." One of the officers of the association informs me that with few exceptions all this work was well received, and Additon states that the interest, inspiration, and suggestiveness of meetings for the training of field workers were encouragements to organizers and older workers. In other words the awakening of thinking women to the share of their sex in the social evil of the world was and has at least begun.

The incidence of venereal disease among men in civil life has been described, but that among women needs statement. The following facts were among the elements in the foregoing awakening. The report of progress of the Section on Women and Girls from November 1, 1918, to January 1, 1919, summarizes a thousand case records as follows: The rule was immaturity, poor education, unskilled labor, deliberate idleness (in face of great demand for all labor), and similar elements of responsibility in the individual as well as society. The report concludes with the following data: Average school grade was 7.3, early cessation of education, tendency toward sex offense (nearly 50 per cent. prostitutes or regularly sexual offenders), majority with venereal infection, and a large proportion involved with enlisted men, fathers of 62.4 per cent. of the illegitimate children. "From these facts it is evident that there is a real need for careful case work to help in the adjustment of the individual woman to the better uses of the community and the nation." Case work has been described as the art of making clear to the individual the nature of his predicament and what the predicament involves. It shows a way out of the trouble and appeals to the motive that helps the person decide to master his predicament and carry out that decision. One of the hopeful signs of the future is that case work of this kind is only beginning, so that what was hitherto impossible is now possible, namely, that this case work may be done among girls who have "lost their virtue" in a community composed largely of the virtuous. Detention of the girl and development of reports are educations for judges. The sanitary law in New York State only recently provides that a person suspected of venereal disease may be detained until its nature is decided by suitable examination.

Education of the industrial interests is of great importance as exemplified by the fact that five times as many men reached camp infected in civil life as developed infection in the service. For this reason, along with other educational activities, that of instructing employees was developed. Printed matter was distributed by toilet and dressing-room placards, by folders, by pay envelope epigrams, by confidential report cards and bulletin boards and leaflets of instruction. It is to be recommended from the standpoint of the civilian specialist that treatment of infected employees in clinics and wards be encouraged. On account of previous ignorance of women the education of women is possibly more important than that of men by exactly the same methods through employers of women. The thought that the native modesty of women is a bar to such a program is the most empty nonsense. In many States women now vote and can no longer hide behind their own petticoats to evade responsibilities in the name of such sham modesty.

The library service was most important and full equipment with buildings and workers was placed in thirty-six camps by the American Library Association, and eight camps had the books and personnel but not the building. The limits of this work are shown by these figures: 185,000 books were supplied to 211 camps, etc.; 130,000 to 111 naval stations; 30,000 to 111 vessels; 20,000 to hospitals, and 200,000 were shipped overseas; 350,000 technical books for study were bought. Men who had never read began the habit of reading and study and grasped chances of promotion and additional knowledge. Dr. Herbert Putman, Librarian of Congress, supervised the work.

Hostess houses aimed to reach women in army and navy stations as visitors of male relatives. Over eighty such bungalow structures were built and special houses were provided for negresses. Their general plan was a large living room with fireplace, spacious veranda, heated and glassed for the year round, coffee-room, rest-room with matron, and nursery. A secretary located the relative sought, and the Travelers' Aid Society met the women at trains.

The War Camp Community Service was a branch of the work which took care of men on leave in communities adjacent to stations. It embraced the following headings which explain themselves: (1) Community Service with information concerning

hotels and like; (2) Community Hospitality developed in clubs, community houses, social centers, dances, suppers, excursions, and the like; "Take a soldier or sailor home to dinner" was a popular movement; (3) Community amusements, in pageants, festivals, parades, and places of amusement with special reference to minimum expense; (4) Community Organization, filling men's leisure with advantageous relations in clubs, societies, Chambers or Boards of Commerce or Trade, religious bodies, and the like; (5) Community Betterment, aiming to prevent financial dishonesty toward enlisted men. In short the aim was to make citizens realize that "preservation of normal social relationship between the people and the men in training is an essential part of our military program."

Law enforcement is another important section of the program. General protection of all arms of the service was proposed by cleaning up communities around camps and stations with aid and by direction of the Government and through co-operation of municipal, State, Federal, and military authorities. Officers and civilians covered military and naval points under the Surgeons-General of the Army, Navy, and United States Public Health Service. The basis was that "Law enforcement breaks down more often from failure to enforce existing laws than from lack of adequate laws." Efficient types of law were found to contain the following provisions: (a) Penalty for letting property for immoral purposes; (b) Injunction to close houses of prostitution; (c) Penalty for solicitation in any form; (d) Penalty for visiting any place for immoral purpose; (e) Annual license of all transient hotels and rooming houses, with revocation for prostitution; (f) Reporting without publicity of venereal disease to health departments; (g) Treatment and supervision of venereal disease carriers by health departments; (h) Reformatory commitment, rather than fines for prostitutes; (1) Rehabilitation institutions for prostitutes, such as that at Bedford, N. Y.; (j) Commitment care for feeble-minded prostitutes; (k) Prompt removal of negligent officials.

An interesting step in legislation is reported from several States. Bills are being introduced making the age of consent apply to boys as well as girls. The State of Washington has enacted the following bill: "An act relating to the carnal knowledge and abuse of children, prescribing penalties therefor, and amending section 2436 of Remington and Ballinger's Annotated Codes and Statutes of Washington.

"Be it enacted by the Legislature of the State of Washington—

"Section 1. That section 2436 of Rem. & Bal. Code be amended to read as follows:

"Section 2436. Every *male* person who shall carnally know and abuse any female child under the age of eighteen years, not his wife, and *every female person who shall have sexual intercourse with any male child under the age of eighteen years, not her husband,* shall be punished as follows:

"(1) When such child is under the age of ten years, by imprisonment in the State penitentiary for life.

"(2) When such child is ten and under fifteen years of age, by imprisonment in the State penitentiary for not less than five years.

"(3) When such child is fifteen and under eighteen years of age . . . by imprisonment in the State penitentiary for not more than ten years, or by imprisonment in the county jail for not more than one year."

Similar bills have been introduced in two or three other States. This, of course, is a new departure, and is directed against the practice of prostitutes carrying on relations with boys under the age of eighteen years. One remarkable feature of the Washington law is that the penalty is exactly the same in punishment for offenders of either sex.

Consistent and persistent attack was made on all prostitution, in redlight districts, public brothels, hotels, rooming houses, and apartments, likewise in its new form, through the automobile, converted into a traveling brothel. Commercial prostitution has been called one of the most profitable businesses and one of the most ancient professions, therefore all law against it has been obstructed by the elements of the traffic itself and of allied traffics, especially liquor dealing. Often interest in prostitution resides in neighboring saloons, mortgage holders, property owners themselves, real estate agents, and the makers and dealers of fineries and similar supplies for women. Therefore, during the war alliance had to be made against these forces by civilians and officials of the Department of Justice and military police, representing the army and navy. A detail was stimulation of official and public opinion from indifference, which connived and encouraged the old order. Citizens' committees and social hygiene societies were organized or recommended, preferably with good lawyers as executives, to know and follow the laws and to coordinate with the police, the prosecuting and judicial sides of municipal government, and indeed to supply any link in the chain failing or lacking. Combined with these duties was education of the public concerning economic, social, physiologic and moral cost of prostitution. Many people do not know the devastation of venereal disease until shown its consequent blindness, sterility, and insanity, and the fact that 90 per cent. of prostitutes are diseased or have been infected. They do not know that the regulation and inspection of prostitutes is scientifically a failure.

Steps taken for men are explained in the foregoing paragraphs, but management of women and girls during the war is less familiar. A Committee on Protective Work for Girls was appointed in September, 1917, with the purpose of "safeguarding young girls from *later* delinquency." The peculiar and to me the most interesting observation in this work is that after six months of purely protective work it was found that the serious problem of camp cities consisted in the *already delinquent* women and girls. To my mind, the former position practically placed all responsibility on the men and denied the law of physiology that the female is of equal importance and responsibility in sexual relations, whether physical or social. To my mind also the latter position is a frank discovery of conditions as they are and not as we would like to have them. In other words, the proper care of the deliberate, intentional, professional prostitute was the real problem of the war, in very large measure.

For the double service of preventive and punitive duty over 100 women officers were appointed at

army and navy camps and stations under seven or more supervisors. The threefold aims were restorative, preventive, and punitive. Restoration was attempted among women who might be induced to return home, by the detection and care of feeble-mindedness, and by the internment for diagnosis and treatment in institutions of women arrested or detained for street walking, with the hope that new impulses in new surroundings would be aroused. In the preventive work prostitutes were made difficult to find by internment or commitment in institutions and by the use of every police method, such as plain clothes men, coordination with military police, revocation of licenses, and the declaration of a building as "out of bound." The last step results in military blockade of such a place. Prevention also involves isolation, seclusion, and treatment of prostitutes and venereal disease carriers. Finally everything rests on a stimulated and educated public opinion, as already stated.

Protection of young women involved appointment of female police, protective and probation officers, and by detention homes in which all the educational, moral, and social elements in each girl's case might be followed. Careful surveillance of all places and forms of amusement, so that the amusements themselves and the older women and all men attending them would be prevented from influence for evil.

Social Hygiene is another section of the work, closely allied to education, in reaching the Army, Navy, and public, concerning the two great facts that prostitution is a spreader of venereal infections and that a combat against venereal disease is necessary.

As already stated, the instruction of each enlisted man was made to cover the nature and the results of these diseases and thus preserve health and fighting efficiency. The measure of the work is indicated by the fact that up to June 1, 1918, more than 1,000,000 men had been reached by all the methods described under education, in camps, and on vessels. A censorship controlled and coordinated all service in this field of unofficial and semi-official agencies, such as civil associations and the fraternal orders. The chaplains were of great service in this

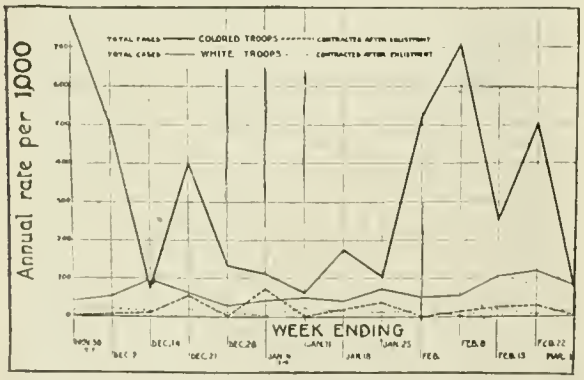

Fig. 2.—Annual venereal disease rates per thousand men, by weeks, in Camp Lee, for colored and white troops, before and after enlistment, from Nov. 30, 1917, to March 1, 1918.

work. About thirty-four camps had sergeants in charge of and trained for this work.

The incidence of venereal disease in the ratio of five cases from civil life before enlistments to one case in military life after enlistment has already been stated, but Snow and Sawyer* add annual rates per thousand men for other important communicable diseases from September 21, 1917, to May 31, 1918, for all troops in the United States: Venereal disease, 102.3; measles, 80.4; pneumonia, 23.11;

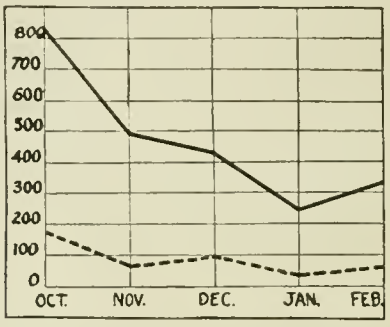

Fig. 3.—Annual venereal disease and prophylactic treatment rates for troops in and around San Francisco, not including cases contracted before enlistment and others obviously not related to San Francisco, showing results of public health measures and law enforcement. Solid line, prophylactic treatments; broken line, new cases of venereal disease.

scarlatina, 5.8; typhoid and paratyphoid, 0.23. Compared with this is the percentage of 4.27 of rejections among 10,000 registrants already quoted from the report of the Provost Marshal General, indicative of venereal presence in the civil population. Injuries and disease by percentages among all troops in the United States from September 21, 1917, to May 31, 1918, ran as follows: Venereal disease, 6.95; measles, 5.46; injuries, 5.22; pneumonia, 1.56; scarlet fever, 0.51; malaria, 0.21; meningitis, 0.16, and typhoid and paratyphoid, 0.016. Thirty-seven special weekly reports from March 29 to May 24, both inclusive from five army camps, gave annual venereal rates per 1,000 men before and after enlistment respectively as follows: Gonococcal infection, 242.3 before and 231.3 after; syphilis, 55.3 before and 53.5 after; chancroid, 34 before and 30 after; total, 337.2 before, 320.4 after. The accompanying chart (Fig. 2) graphically compares colored and white troops.

The accompanying table (Fig. 3) illustrates the value of the Social Service campaign. It graphically gives a line for prophylactic treatment which may lead away from the influence of all other elements in diversion, education, moralization, and motivation. The question may be asked, where in former wars did enlisted men spend the time consumed in this war in all these new relations? And can such time have counted for little in comparison with prophylactic treatments?

Men's Work is a department allied to the Law Enforcement Division and addressed itself to citizens for investigation of local vice conditions and for effective respect of existing laws or development of new laws. Local committees sought to close restricted districts and initiate venereal education, especially in industries. They were backed by public opinion and by new regulations in local and State Departments of Health. Snow and Sawyer state that at Camp Lee a psychological study was made of 12 per cent. of the negroes and 2 per cent. of the whites then isolated for venereal disease. Thirty-four per cent. of the whites were unable to read or write English required by the tests, compared with

*Venereal Disease Control in the Army.

18 per cent. of equal illiterates in the whole camp. Venereal whites taking the tests scored 75 per cent. of the camp average. "Moreover, less than half as many of the diseased white men, in proportion to total numbers, obtained high scores, as did the white men in the camp as a whole." Low mentality increases probability of infection, and indifference to cure and success against venereal disease must reach this class. Parallel with this fact is a statement to me by Dr. Amos O. Squire, the prison physician of Sing Sing Prison: " . . The last time a series of 800 cases were studied, it was found that 60 per cent. were below the mental age of twelve years and that 70 per cent. of them were recividists, that is, men who have been either in this or some other institution before." It is well known that nearly all prisoners have or have had venereal disease. I have heard the percentage given as high as 90. Likewise in comparison are the statements given by Rippin* proving that a very large per cent. of voluntary professional prostitutes are of low mental capacity, poor education, mental deficiency and definite degeneracy shown by truancy, incorrigibility, alcoholism, other drug habits, and criminality. I repeat that one may no longer charge the bulk of the venereal problem against either sex alone, and the sooner the women of the community realize the responsibility for their own sex, the better.

Women's Work in Social Hygiene develops education concerning the fact, nature, and incidence of venereal disease and the responsibility and control of women in cleaning up camps and towns. Recent suggestive results is a resolution in the Federation of Women's Clubs in a large city stating that modern dress styles are improper and indecent. If this vote is more than talk a very potent temptation of men by thoughtless, otherwise virtuous, women will cease. Like myself, every urologist each year treats large numbers of men infected with venereal disease acquired on their way home from balls after hours of temptation through indecent feminine attire. It is fair to state that a woman has no more right to expose her person than a man has. Women must know in plain English that the common decolleté ballroom gown is the rule in every brothel where its purpose of direct sexual excitement of the men is intentional and "commercial." The unintentional excitement of these gowns in ballrooms should be stopped as a matter of common sense. When women hear and heed this lesson they will have gained wisdom.

Other parts of the work are sex education of children in homes and schools, of girls and young women, chiefly by trained physicians and by literature and exhibits in aid of public health boards, child welfare and civic societies. The incidence of venereal disease or temptation among women is now known to proceed not only from psychological defect but from civil disadvantages such as poverty, parental neglect, evil companions, and improper training.

Exner† distinguishes sex *information* from sex *instruction*. His paper is worthy of careful study. He found that the average age of first permanent sex *information* was 9.6 years and that boy associates were the sources in 544 cases, girl associates in 33, male hirelings in 22, and female hirelings in 5. These groups reached 604 among 676 answers to this question. A sad contrast in the same group are parents and relatives 27, brothers 14, sisters or cousins 3, in total 44. In percentages, 91.5 per cent. were evil or imperfect sources, and only 4 per cent. were parents. The natural outcome by confessions in the answers was evil influence in 79 per cent. and good influence in 8.8 per cent. Of 61 men benefited by the *information*, 29 were taught by parents or close relatives, 13 by responsible persons, and 2 from reading. Bitterness against parents for *non-instruction* was often expressed. The foregoing shows that parents and teachers cannot prevent sex *information*. It is their privilege to determine what kind of sex *instruction* children receive.

A parallel of the foregoing situation is that the average age of *sexual practice* in some form was 13.4 years; 6..1 per cent. began sexual practice *before* puberty and *before* the period of conscious sexual activity and *before* really pressing sexual impulse. To this may be added that self-abuse began at the average age of 12.8 years and actual intercourse at 15.

In a different group of college men he found that 94.5 per cent. had received sex *instruction* from responsible sources, at the average age of 15.5 years, just six years after the age of first permanent sex *information*, just stated, 9.6 years. In this same group 87.6 per cent. received permanent impressions before the thirteenth year and only 13.4 per cent. any wholesome instruction at the same time. The sources of instruction were relatives 22.5 per cent.; literature, 20.1 per cent.; lectures, 10.6 per cent.; schools, 18.4 per cent.; religious, 8 per cent.

Exner notes growing interest in sex education by school authorities and teachers. This is a very hopeful and righteous sign.

In contrast with the dismal showing of the cases of sex *information* this group with sex *instruction* reported good influence in 90 per cent. and bad influence in 1.2 per cent. Of 401 men acknowledging sex *instruction* 10.5 per cent. started sex habits after it, 60.4 per cent. before it, 14.7 per cent. stopped on account of it, 5.2 per cent. made honest effort at control after it, 6 per cent. were prevented from indulgence by it, and 32 per cent. developed self-control after it, in total 29.1 per cent., not far from one in three.

It is difficult to understand how in the presence of such indications as these not a few but many well-meaning but prejudiced and misguided persons should still object to high-minded and responsible *sex instruction*—on the poetic and alliterative ground that it is the "repeal of reticence"!

Protective Work among girls has been described with omission of the detail of teaching trained workers of broad viewpoints. Accordingly special field work instruction was given at the New York School of Philanthropy, the Chicago School of Civics and Philanthropics, and the Boston School of Social Workers, respectively, in cooperation with the Girls' Protective League, Juvenile Protective Association of Chicago, and Women's Patriotic League of Massachusetts. Protection and supervision of

*Municipal Detention for Women.

†Problems in Principles of Sex Education, A Study of 948 College Men, Y. M. C. A. publication.

girls were taught in all relations in camps, parks, places of amusement, dances and the like.

A needed detail, not fully reached during the war, was uniform and universal Government control and regulation as to women both as workers and visitors in any and all military stations; likewise, adequate housing and amusing of women workers exactly paralleling the Government's own conclusion concerning the men that respite and recreation from arduous duties must be supplied for idle times in order to keep sexual temptation away. Such regulations would be analogues of reprints 459 and 485 from Public Health reports, respectively "Suggestions for State Board of Health Regulations for the Prevention of Venereal Diseases" and "Regulations Governing Allotment of Funds for Venereal Disease Prevention Work." The allotment of funds for prevention of venereal disease under the Chamberlain-Kahn Bill was, institutional 50 per cent., educational 20 per cent., repressional 20 per cent., and administrative 10 per cent. Williams* states that the discoveries of the *Treponema pallidum*, salvarsan and complement fixation test are landmarks. He omits acknowledgment of the influence of alcohol on the Wassermann test which, in my opinion, marks a chief fault because dishonorable patients in marital or commercial relations may destroy the test with alcohol. But the test remains a valuable index in marriage, life insurance, morbidity in industrial and compensation insurance, recruiting for Government service and examination after induction. It would be important for social, commercial and professional bodies and in prophylactic work.

Prevention necessarily includes examination of women, and statistics have been found by Rippin: Among 750 examined, 278 had gonococcal infection, syphilis, or both. My own opinion is that no diagnosis among women can be made without the preparation of eight slides: two each from vulva, urethra, vaginal cul-de-sac, and cervix. Additon says that of 5,280 women examined, 1,118 had venereal disease. This record, in my opinion, is suspiciously low and tends to indicate lax methods. The absolute thoroughness of examination should be uniform in order to make statistics worth while. A long step is the public clinic, ward, and detention home. Up to February, 1919, there were 102 clinics and 33 detention homes controlled by the United States Public Health Service. The Government controls 25 clinics in extracantonment areas. Detention homes have 1,950 beds, of which 1,125 are in two State penitentiaries and one county jail. It is noteworthy that the Government knows the importance of bed care. This knowledge is still to reach the civil community and the average hospital. Physicians and druggists themselves were appealed to by the Government to know and act on their share of responsibility. Physicians largely do not recognize the importance of venereal disease in either sex, and druggists are guilty of encouraging self-treatment by "across counter prescribing." The Government has set itself against both these mistakes.

Results during the war itself were primary and consisted in abolition of many redlight districts and of brothels where no districts existed and the suppression of prostitution at least in the immediate neighborhood of camps. All regions with which enlisted men were familiar were so far as possible reached, and many States have special organizations with secretaries, such as California, Arkansas, Minnesota, Texas, Virginia, and Maryland. In January, 1918, there was . . . not a single redlight district within five miles of any cantonment or military camp or naval station where any considerable number of soldiers and sailors are training."*

The most vicious form of liquor traffic, "bootlegging," by sale or gift to soldiers, was checked by heavy fines and long terms. The application of military regulations for the discipline of infected men has already been discussed.

Among women, Falconer† covers the lessons in about the following terms: Prevention, by all known means; clinic and hospital treatment of the infected; probation in all its relations; employment with training therefor; commitment to industrial rather than punitive institutions; intelligent, broad-minded management of such institutions, by executive women with forceful staffs of educated young women and not sentimentalists or faddists; cottage plan for inexpensive, serviceable buildings, with money put into salaries of proper personnel rather than into ornate structures; staffs consisting of physicians, psychologists, ophthalmologists, dentists and farmers; large tracts of land for outdoor instructions; separation of hopeful, nearly normal women from hopeless and defective women, whites from colored cases, Jews from non-Jews; nonsectarian organization with respect for special beliefs; indoor work secondary to outdoor work, in farming, gardening, athletics; indoor work largely manual, in basketry, weaving, domestic science and music, and on the mental side English, arithmetic and simpler branches; sports, diversion and entertainment prominent; wholesome, abundant food, simple washable apparel, and finally a judicious system of parole and aid.

The organization should continue by which local committees develop the work among young women by their seniors having reputation and confidence through conferences, club meetings and the like, to evoke earnestness, sincerity and comprehension. The interest of employers in these matters should be maintained.

Snow and Sawyer give the following conclusions, although it is reported that the American Expeditionary Forces were the cleanest in history: (1) Venereal disease is the greatest cause of disability; (2) Five-sixths of the cases are contracted in civil life before enlistment; (3) Exposure is being successfully reduced by education, recreation, law enforcement, control of disease carrier; (4) These measures are of service in civil as well as military communities; (5) Venereal control should be under both public health authorities and civil agencies in cooperation, for education and law enforcement; (6) Venereal disease is reduced by early prophylaxis; (7) Reduction of venereal disease is the present greatest public health problem, with promise of

solution through efficient, already demonstrated measures.

Future plans are accordingly of importance and point to the need of continued civilian organization. Mr. Robbins Russel, Associate Director, Men's Section, Social Hygiene Division, War Department, Commission on Training Camp Activities, has stated to me that the New York office has received 35,000 letters from live business men in 800 communities which had never before had an open statement of the problem. These letters express appreciation, gratitude, and cooperation rather than mock and foolish modesty. Of great importance is the fact that these letters admit the necessity of venereal clinics and wards. Thus it looks as though the small communities will be in advance of the larger ones on the very important point of so organizing their hospitals that venereal cases will not be declined but deliberately admitted to ward service. No hospital can possibly do its duty by the community unless it has wards for venereally diseased men, women and children. Furthermore, when the laity fully awake to this fact there must be a shake-up in those hospitals in which the general physicians and the general surgeons have selfishly excluded all cases but their own.

The Young Women's Christian Association has learned and will apply the value of its educational films and lectures. These were so well received that the campaign will continue, changing only from the strictly military side of the venereal problem to the fundamental social side in sex morality for women.

Perhaps the greatest lesson for the comunity has been revealed by such institutions as the House of Detention for Girls and Women, connected with the Municipal Court in Philadelphia. It affords the proper residence and study of women arrested for sexual and other charges. Two distinct groups were manifest: (*a*) habitual street walkers, and (*b*) younger incorrigibles and runaways. The responsibility of society is exemplified by the fact that in 1917, 1205 girls and women were investigated in Philadelphia. Sixty-three per cent were unmarried, whereas the average marriage age is from 20 to 24 in that city. The greatest street-walking prostitution was 344 cases between the ages of 20 to 29, embracing the aforesaid marriage period and corresponding with the age of men for the first draft. This fact speaks volumes for itself on the point that in both sexes when the fires of passion burn hardest both men and women sin most. During the same decade only 52 were classed as runaways and incorrigibles, in other words, the street walking was deliberate and intentional. The greatest delinquencies were 565, between the ages of 16 and 19, when youthful will is strong but judgment weak. Only 67 of these were street walkers, leaving practically 500 in the truancy group.

The responsibility of society is further shown by the fact that 828 of these women had left school before their fifteenth year, 143 before their sixteenth year (a total of 971 before their seventeenth year), and between the sixteenth and nineteenth year, 213. The relation between education and low wages is revealed by the fact that a few were show girls at $19.00 per week, others bookkeepers and stenographers at $10.00, 49 in total; habitual idlers and without known occupation, 147; leaving all others at wages varying from $4.00 to $8.00. Mental and nervous instability and defect shown in drug habits (alcohol alone, narcotics alone, or both combined) cover 385 cases, of which 322 belong to street walkers, incorrigibles, and runaways. Of the 820 denials many were probably falsehoods. Here again, comes in the importance of examination and separation of defectives from normals. Additon states that of 88 women examined, 42 were found to be feeble-minded. In the protection of society against these women and of the women against themselves, no steps are wiser than the detention home, periods of probation, legislation for enforced care of venereal disease carriers, permanent custodial care for the feeble-minded delinquent and the like, not because they are women and potentially prostitutes, but because they are actually defective and real economic losses and dangers to the community. Such work can be done only by case work among women which means that the virtuous women of the community may no longer with smug indifference regard their fallen sisters, but that they must with broad and scientific spirit recognize them as a curable element in social disease and disorder. Such women must begin with the conviction that the venereal peril is by no means created by men alone.

Industrial development of this problem is new and without distinct statistics as to educational and medical results but the Commission on Training Camp Activities reports to me that the call for educational aid continues. A salient fact is that inquiries reached the Commission directly and indirectly from working people themselves asking for and thanking for the pamphlets and other instruction received. Coming as these requests do from that stratum of society in which poverty often leads to sexual immorality, they become of first significance. Among railroads, the Long Island system is the first to place suitable pamphlets and placards for the study of its employees.

The importance of work among the employees of hotels and restaurants and similar food-handling industries cannot be overstated, as illustrated by the following fact. At Fort Worth, Texas, the United States Public Health Service made a survey of all food handlers and found that 10 per cent. of the entire industry, more or less directly associated with hotels and restaurants had venereal disease in infectious status. Practically all large hotels in this city have medical inspection of their employees and some even manicure the nails of their kitchen and restaurant departments. But what a mote such care is as compared with the beam of venereal disease in the eye of hotel management. The policy adopted by one large factory known to me should be universal. It is that no employee, man or woman, may be absent on sick leave without proving to the management that it was not for venereal disease. Skillful men and women physicians alone are necessary for such a system of certification. In this corporation the fact of venereal disease does not act against promotion but the system prevents all danger of infection of innocent persons. No such definite plan among hotels in this city exists nor even in the New York Depart-

ment of Health, except that through the Bureau of Food and Drugs, hotels are inspected as to their food supply, and known venereal disease among all food-handling industries is imperfectly controlled by the Bureau of Preventable Diseases. The inspectors of this Bureau and the Bureau itself may withhold licenses from disease carriers.

The willingness of industries to cooperate with the Government is shown by the action of the Liquor Dealers' Association of this city at the request of the writer when the Government appeal was issued early in 1918. I called together a meeting of the Presidents of the Association of each borough, five in all, and obtained their ready promise and consent to remove from their beer saloons improper and illegal signs advertising proprietary medicines, quack treatment, and the like as to venereal disease. This session occurred a few days before the annual meeting of the State Liquor Dealers' Association and at my suggestion the president of the Manhattan Association, seconded by the president of the Brooklyn Association moved that the same campaign be carried on throughout New York State. Subsequent reports were made to me by these presidents to the effect that it was believed and as far as possible known that a clean sweep of all such advertisements had been made.

Further in the industrial field in the present and for the future the United States Public Health Service have reached about 36,000 establishments. Much still remains to be done because only 1,000 firms (about 3 per cent.) have favorably responded. Nevertheless these have bought in round numbers 700,000 pieces of educational printed matter and by their own presses have increased this quantity to perhaps over a million. As examples, one large mining corporation reprinted the material in English and Spanish and induced all civic and welfare workers, churches and schools in the six towns of their establishment to cooperate. Another concern reprinted the literature in English and Polish and established clinics under a competent specialist paid in part by the company and in part by the patients. A large foundry recorded that 25 to 30 men per thousand applied to their venereal specialist and in another district 10 per cent. The difference is due to the large number of unmarried men in the second group.

Such facts foretell the need of definite effort in the future along venereal instruction and treatment in industry. Casualty insurance companies are interesting policy holders because injury to the venereal patient is apt to be more serious than to others. The educational campaign aims to induce employers to set aside a portion of their budget for venereal disease education and treatment exactly as for first aid instruction and treatment.

On the side of the Government it is to be noted that the war seems to have proved to it the wisdom of including a venereal research under the studies and survey of industry within the jurisdiction of the Division of Industrial Hygiene.

A very hopeful sign is that many employers who previously discharged the venereal victim are now retaining, instructing, and curing him. This is somewhat parallel with the fact that the young female sex offender is no longer immediately made an outcast but given a fair and free chance to make good, even among and by the smug virtuous, of whom probably many never in their lives had a real sex temptation or a positive sex impulse.

Lastly labor organizations are beginning to accept the suggestion that courses of instruction among their members will be of value.

In the absence of statistics from the War Department it is manifest that this paper cannot contain final deductions in those portions which deal with Governmental relations in the military service.

Many valuable pamphlets have been issued by the Government and civil bodies, and I will close with a list of the most serviceable, of which I have made free use and for which due credit is now given.

LITERATURE.

Army Pamphlets.

"Keeping Fit to Fight" (blue eagle cover), "Keeping Fit to Fight" (colored edition), "Keeping Fit to Fight" (edition with soldier cover), "Sword of Damocles," "Special Warning to Recruits," "Hello, Soldier Sport," "The Wise Guy," "Colonel Care Says," "Will They Ever Make One Out for You?" "Carry On," "Your One Big Battle," "Putting It Up to the Boys," "Letters from Home," "Back in the Good Old U. S. A.," "A. E. F., the World Is Watching You," "The Girl You Leave Behind," "When You Go Home," "Fit to Win" (story of the motion picture drama), "Dear Buddy Letters," "V. D., Putting It Up to the Men," "Smash the Line," "The End of the Road" (the story of the moving picture drama), "Keeping in Fighting Trim," "V. D., Facts for Every Man."

Navy Publications.

Educational Exhibit No. 4, consisting of twenty placards. Set of ten posters, "Surgeon Sage Says." Set of sixteen posters for small ships, Exhibit No. 8. Posters for heads. Pamphlet, "Live Straight if You Would Shoot Straight." Pamphlet, "The Rookie Puts One Over on the Old Shellback." Pamphlet, "Carry On" (for patients in venereal wards). Pamphlet, "Combating Venereal Disease by Educational Methods." Pamphlet, "Is It Worth While?" (circulated among medical officers). Folder describing facilities of the section. Folder, "Shore Leave." Folder, "The Girl You Leave Behind." Folder, "Give Yourself a Square Deal."

Public Health Service Pamphlets.

"V. D., Keeping Fit," "Responsibility of Druggists to the Public Health," "Fit to Fight," "Keep Them Fit," "The Attack on Venereal Diseases," "Manpower," "The Problem of Sex Education in Schools," "The Need for Sex Education," "Why Should High Schools and Colleges Provide Sex Instruction?" "Venereal Disease—A Public Health Problem for Civilian," "Communities," "When They Come Home," "War on Venereal Disease to Continue," "An Appeal to Advertising Media to Cooperate in the Fight Against Venereal Diseases," "Shall We Finish the Fight?" "Venereal Diseases and the War," "Come Clean," "The Government Has Declared War on Venereal Diseases" (placard), "Important Confidential Information," "The Right Steer," "An Appeal to Physicians for Cooperation in the Fight Against Venereal Disease," "Disease and Health," "A Message from the Government to the Churches of the United States," "The Need for Sex Education" (V. D. No. 9, with book list added), "Lectures on Social Hygiene for Nurses," "The Public Health Nurse and Venereal Disease Control," "The New War—Fighting for Health. To the Soldier with His Face Turned Homeward," "Keeping Fit.—An Exhibit for Older Boys and Young Men" (containing miniature reproductions of the Health Exhibit), "A People's War."

Y. M. C. A. Pamphlets.

"Friend or Enemy," "The Rational Sex Life for Men," "Life's Clinic," "The Dynamic of Manhood," "The Nurse and the Knight," "Don't Take a Chance."

Y. W. C. A. Pamphlets.

"Who Shall Buy My Clothes?" "What Shall I Wear?" "Girls—A Home Guard," "Mothers All," "Am I Ashamed of My Job?" "Heroines of Health."

45 West Ninth Street.

MEDICAL RECORD.

New York, July 19, 1919.

A GREAT AMERICAN AND A GREAT PHYSICIAN.

IN the death of Dr. Jacobi, America as well as the profession of medicine, has lost one of its great men. Although not in politics, Dr. Jacobi was largely in public life and was, in a quiet way, a power for good in the country. Born a German, there was never a Mayflower descendant whose Americanism was more genuine in feeling and more positive in expression than his. He had learned by actual experience the evil of Prussianism, and when, five years ago, the Hohenzollern and their robber barons began their predatory invasion of their neighbors' lands, Jacobi was among the first to recognize it for the despicable thing it was, and he let no counsel of neutrality, no inward call of the blood, no outgivings of German State-paid professors dissuade him from warning his fellow countrymen of the true meaning of that rush to loot.

But while ever giving to his fellows an example of what a good citizen should be and while always ready to take up his pen in defense of what he conceived to be the right, it was as a medical man that he gained and held his supereminence. Coming to this country before most of those now acknowledged as leaders of the profession were born, his influence was always potent in shaping the course of medical progress. He early recognized the fact that the child is father of the man, physically as well as mentally and morally, and believing that the hope of the nation was in its children, he set about the salvation of the State by safeguarding the health of the new generation, and so became the father of pediatrics. But it was not only as a children's doctor that he functioned, for he knew that without healthy parents there could be no healthy children; indeed, nothing medical was foreign to him, and in all questions pertaining to general medicine, therapeutics, and public health he was an acknowledged leader.

Dr. Jacobi was a man of enormous vitality of mind as well as body, erudite, and of an inexhaustible capacity for work, a writer of clear English, and a convincing speaker—a distinguished citizen and a learned physician. In fact, in whatever direction he employed his incomparable gifts his mastery was easy and complete.

THE SYMPTOMATOLOGY OF ANGIOMATA OF THE ORBIT.

THE most constant and at the same time most striking symptom of angioma of the orbit, is exophthalmus, whether the growth be the simple or cavernous type. The bulging of the eye will vary according to the size of the growth. Digital compression of the jugular vein may cause it to increase and during the menses the tension also is apt to be marked. The exophthalmus may be in the axis of the orbit or the globe may be deviated in different directions. The former type appears to be the more infrequent while internal deviation of the globe is the commonest.

When the tumor is large the orbitopalpebral sulcus is occasionally effaced or the neoplasm forces one of the lids upward with the result that it is put on the stretch and therefore thinned and tense. If the lid be raised the tumor can be seen, usually offering a bluish color. It is not uncommon for an angioma of the orbit to coincide with one on the lids or neighboring skin and unless there are corneal complications resulting from an exaggerated exorbitism, the globe retains its shape and size. The tumor will be found firm, elastic, but not hard in the cavernous type of angioma, although in some cases it may offer a certain softness, which is more prone to be present in simple angioma. This latter type of tumor has indistinct limits, while the cavernous type offers distinct relations to the orbit and globe, at least in those portions accessible to palpation. A cavernous angioma being usually encapsulated it is from this fact, usually quite independent of the surrounding structures.

Some writers admit as an important diagnostic sign, a compressibility of the growth, but in simple angioma, excepting the lipomatous type, the compressibility is not marked, and when it can be elicited the tumor is probably of the cavernous variety. Fluctuation is exceptional while expansive movements probably never occur in true angiomata of the orbit, neither do pulsations exist in simple angioma, while in the cavernous type the certitude of their existence has yet to be proved, the few cases where they were supposed to exist were probably not instances of orbital angioma but rather aneurysmal in nature.

The ophthalmoscope gives variable results according to the consistency and site of the tumor. When yet small, and therefore exercising no compression on the vessels and nerves of the region, the fundus will be absolutely normal, but when the growth has acquired a certain size and firmness, consequently compressing the vessels and nerves of the orbit, there may be a dilatation and flexuosity of the retinal veins, a perivascular suffusion, or even an optic neuritis, characterized by an atrophy of the papilla and retina, indices of optic nerve compression. The reactions of the pupil to light and accommodation remain normal in most cases, but the pupil may become paretic and the field of vision may become narrowed, while in one instance there was a central scotoma.

The most important subjective symptom is a gradual diminution of visual acuity from pressure on the optic nerve, and complete loss of sight has been known to occur, although in very few cases. Pain is rarely complained of, and when it does occur it is after the growth has produced a marked degree of exophthalmus. A third sign of importance is the integrity of the muscular play which is maintained for years, it being present in 70 per cent., and more or less interfered with in one or all directions in 20 per cent. of the cases, while in only 10 per cent. was it abolished, in which case the absence of movements resulted from the large size of the tumor. Occasionally, diplopia and strabismus have been noted.

Angiomata of the orbit are slow in development, requiring years before producing an exaggerated exophthalmus or the appearance of a mild degree of pain. An angioma which has been stationary for a long time may, from some unknown cause, suddenly take on a rapid development, while on the other hand the inverse condition arises, and a rapidly developing tumor may suddenly slow down in its evolution and afterward follow the habitual slow progress of these neoplasms.

The lymph nodes are never involved and the patient's general health is good. Occasionally a coincidence of orbital angioma with some other affection of the region has been noted, such as encephalocele or hernia of the meninges filled with cerebrospinal fluid. Once the angioma had developed behind a cyst of the orbit, while the coincidence of orbital angioma and hypertrophy of the thyroid has been noted. Malignant transformation of orbital angioma has been known to occur, the case recorded by Sokolof being an undoubted example, and in one case the growth became inflamed during typhoid fever, an abscess developed, and the pus contained the bacillus of typhoid.

To sum up, the principal symptoms of angiomata of the orbit are: an exophthalmus, frequently with a decrease in the visual acuity; a firm and elastic consistency when the growth is of the cavernous type; preservation of the ocular muscle play for years; slow progress; absence of pain; and last, the maintenance of excellent general health.

THE RÔLE OF THE PORTAL VEIN IN THE GENESIS OF HEPATIC ABSCESS.

The portal venous system, of all the routes reaching the liver, whether arterial, lymphatic, or biliary, is the one through which infection is the most prone to travel. The portal vein collects the venous blood from all the abdominal viscera with the exception of the liver and kidney. Besides the portal vein the liver receives blood from the gastro-epiploic and cystic veins, the small venules from the under surface of the diaphragm and the small network of parumbilical veins. This really immense venous system, the roots of which lie in every corner of the abdominal cavity, explains why a suppurative process in any one of the abdominal viscera so frequently gives rise to abscess of the liver, and this is especially true of tropical abscess of this gland.

Intrahepatic suppurative processes are primarily seated in the interlobular connective tissue and the vascular lesions unquestionably play an active part in the process. However, it is occasionally difficult, when an intravascular blood coagulum undergoes purulent transformation, to decide whether the clot is a primary or secondary formation. Very anfractuous abscesses and venous thromboses may be found at necropsy, yet it may be difficult to determine if the latter were the cause or the consequence of the suppuration. Abscess of the liver is caused by a phlebitis of the umbilical vein and all the viscera whose circulation is tributary to the liver can cause it. It has followed cauterization of rectal cancer, operation for anal fistula, and the radical cure of strangulated hernia where the reduced omentum ultimately suppurated. The operation for hemorrhoids has resulted in hepatic abscess and a phlebitis of the splenic vein has had the same result.

Inflammatory or ulcerative processes of the digestive tract are those that give rise to hepatic abscess above all others. The liver process has occurred as a sequel of gastric ulceration, while ulcerative processes of the small intestine are more frequent causal factors hepatic abscess than the former, but in this respect the immunity offered by the liver in the vast majority of cases of typhoid fever, and especially in tuberculosis of the small intestine, is quite remarkable, although suppurative hepatitis is not unknown in typhoid. However, the most frequent starting point of abscess of the liver is in the large intestine. We do not refer merely to specific ulcerative processes, such, for example, as dysentery, because a simple colitis with destruction of the mucosa may result in similar consequences. Appendicitis is not unknown to cause suppurative processes in the liver, and all these facts, which could be multiplied, simply go to show the close relationship existing between ulcerative processes of the gastrointestinal tract and abscess of the liver.

The suppurative hepatitides may result from a phlebitis by extension, and it is certain that phlebitis of the mesareic veins or of the trunks of the portal vein plays an important part in the etiology of the liver process. But phlebitis by extension is applicable to only a certain number of instances, and it is an unquestionable fact that emboli play a big part in the genesis of hepatic abscess. The embolic theory has only one fault, that of insufficiently explaining the formation of metastatic abscesses, because it is difficult to admit that emboli can pass through the pulmonary capillaries and become lodged in the intrahepatic capillaries.

Referring now to tropical abscess of the liver which does not depend upon a dysentery, it is still the intestine which is the starting point of the process. The *Bacterium coli*, the staphylococcus, and other pyogenic bacteria inhabiting the gut can easily reach the liver through a solitary erosion or ul-

ceration of the intestinal mucosa. If an abscess of the liver results from the penetration of the hepatic parenchyma by pyogenic bacteria it may very well happen that this abscess may undergo its evolution at the same time as a dysentery. It can also be understood that an already formed hepatic abscess may, by the portal stasis it produces, diminish the resistance of the intestinal mucosa and thus favor the development of dysentery.

A Hitherto Undescribed Tremor Seen in General Narcosis.

A study of the general subject of tremor and a perusal of the large monographs on surgical narcosis have failed to disclose any reference to a certain phenomenon seen by Rietz in 28 subjects anesthetized during the past seven or eight years. In *Hygeia* for April 15 the author gives a full account of the manifestation. Anesthetists naturally pay much attention to any kind of behavior which interferes with the development and maintenance of the narcosis; hence the silence on this particular manifestation is the more strange because in some cases it was very burdensome for the author. The tremor consisted of rhythmic muscular contractions which at times were so violent as to merit the name of clonus. The lower extremities were the chief seat of the disorder which at first suggested some form of cortical motor irritation, either a very wide tremor or epileptiform convulsion. The motor disturbance set in abruptly and without prodromes, and as a rule with full intensity. The movements persisted for a longer or shorter interval and ceased as abruptly as they began, the operation being held up for five minutes or more. The author analyzes his material exhaustively. All but one of the patients were males in the most vigorous ages—25 to 40. The tremor developed at any period of narcosis but in the small material analyzed there was a predominance of cases at the close of the period. Of the 14 cases in which this particular was noted the tremor in 3 began at the induction and two more in the first half of the narcosis. There was a single case which occurred when the narcosis was half over, two in the last half and six at the close. In one case the condition persisted throughout the entire narcosis. Ether was used in 23 out of the 28 cases. Of many interesting features mentioned the most remarkable and practical is that the motor disturbance could be controlled by compression of the carotid arteries.

Cancer and the War.

The increasing number of believers in the unfavorable influence of overalimentation on the genesis of cancer have awaited with impatience some corroboration or the reverse of this belief in connection with the extreme malnutrition of the great war. Other elements, such as innumerable traumatisms and possibly psychic factors, also have to be considered in the same connection; so that while one factor may antagonize cancer another may foster its spread. The first reports come from the troops and as these are nominally receiving a balanced ration sufficient for great exertion we can hardly look for evidence for or against the nutritive factor. In troops, moreover, the cancer age has hardly been reached, although many cases occur on the sunny side of 40. An article by Forgue, cited in the *Journal de médecine et de chirurgie pratiques* for March 25, makes public the information that of 200,000 soldiers, either dead or mustered out for disease, but 486 had cancer. The period of record ended April 1, 1918. There was hardly a case under the age of 30. Of the total given above 179 occurred in subjects between 40 and 45 and over one-half were cancers of the stomach. But 19 cases showed a traumatic factor. The late Dr. Murphy's axiom is strengthened that sarcoma follows the single lesion and cancer (epithelioma) the chronic repeated irritation. There was nothing in any case to suggest that cancer could have been due to infection from without although opportunities of all kinds were abundant. The actual causal factors, save for smoker's cancer and the like, could not be elicited. Malnutrition and fatigue are mentioned as possibilities, but without evidence.

News of the Week.

Yellow Fever Again Epidemic in Yucatan.—According to a report sent to the *Excelsior* of Mexico City, yellow fever has broken out at Merida, Yucatan. Vigorous action has been taken by the port officials to prevent a spread of the disease.

Ravages of Influenza in Samoa and Alaska.—A delayed message from Apia, Samoa, states that that island has been ravaged by influenza. Of a total population of 38,173, 3,265 men, 2,704 women, and 1,574 children have died. A report has recently been received at San Francisco confirming previous rumors as to the ravages of influenza among the native Indians of Bristol Bay, Alaska. According to Lieut. W. R. Leahy who headed the relief expedition to the North, 95 per cent. of the population of 900 persons had died by the time the expedition reached Bristol Bay.

Demobilized Men Healthy.—The War Department reports that for the week ended July 5 there was a continuation of the excellent health conditions of the army both in this country and in Europe. More than 93 per cent. of the 2,000,000 officers and men of the army who have been discharged since the signing of the armistice left the army with a clean bill of health. Of the remainder, 6 per cent. were reported to the Bureau of War Risk Insurance because of disabilities and one per cent. were kept on account of communicable diseases. The negro troops showed a slightly better physical condition than the whites but a higher percentage were held for communicable diseases.

Plan to Make New York a Greater Medical Center.—A concerted effort is being made to develop in New York a medical center similar to those of Berlin and Vienna before the war. An organization to be known as the New York Association for the Advancement of Medical Education and Medical Science has made an application for incorporation to the office of the Secretary of State at Albany. A constitution and by-laws have been adopted setting forth the objects of the association. The new organization has elected the following of-

ficers: *President*, Dr. Wendell C. Phillips; *First Vice-President*, Dr. George David Stewart; *Second Vice-President*, Dr. Glentworth R. Butler; *Secretary*, Dr. Haven Emerson; *Treasurer*, Dr. Arthur F. Chase; *Trustees*, Dr. Charles H. Peck, Dr. William Francis Campbell, Dr. John A. Hartwell, Dr. Frederick Tilney, Dr. Otto V. Huffman, Dr. Arian Lambert, Dr. Samuel A. Brown, Dr. James Alexander Miller, and Dr. George W. Kosmak.

New York's Death Rate Drops.—The records of the New York Health Department show that for the week ended July 5 the death rate for the Greater City was 9.47 per thousand. For the corresponding week of 1918 the rate was 10.14 per thousand. This was the fourth consecutive week that the death rate had fallen below 10 per thousand. The death rate for the first 27 weeks of this year was 15.02, which is .39 higher than for the corresponding period of 1918. Only 31 deaths were reported during the above mentioned week which is one-half lower than the record for the corresponding week of last year. The infant mortality rate shows no change from that of a year ago.

Physicians Warned to Register.—Commissioner Herrick of the State Department of Narcotic Drug Control has sent out a special notification to 9,000 physicians, dentists, and veterinarians who prescribe or administer habit-forming drugs and who had failed to register, that unless they complied with the law by July 10 they were liable to criminal prosecution. On July 1 only 8,000 of the 17,000 dispensers of narcotic drugs had complied with the law. Commissioner Herrick states that in dealing with evaders two courses are open to the department. In the discretion of the Commissioner licenses may be revoked or evaders may be prosecuted as violators of the public health law.

Debarkation Hospital Closes.—Debarkation Hospital No. 3, at Eighteenth Street and Sixth Avenue, New York City, closed its doors on July 15. This hospital was the largest military hospital under one roof in the world, and has received and evacuated more cases in a shorter time than any other institution of its kind in the United States. Since the first consignment of wounded men arrived on November 23, 1918, a total of 36,878 patients have been entered and later discharged or transferred to hospitals nearer their homes. The average number of beds occupied daily was 2,469. The personnel of the hospital included 101 medical officers, 306 nurses, and 962 enlisted men. The record number received in one day was 2,235, and the largest number discharged in one day was 1,638. Lieut. Col. William J. Monahan, the commanding officer, was the guest of honor at a dinner given recently where he outlined the work of the hospital.

Addition to Institution for Feebleminded.—Governor Smith, on July 10, laid the corner stone for a girls' dormitory at Letchworth Village, near Thiels, Rockland County, N. Y., which with the other buildings to be put up this year will give accommodations to 840 additional patients. At the recent session of the Legislature $880,000 was appropriated for new construction at the village to meet the great need for institutional accommodations for the feebleminded. Dr. Pearce Bailey, who was recently appointed chairman of the State Commission for Mental Defectives, made an address in which he urged the establishment of an adequate probation system and the extension of research work at the village.

To Organize New Hospital.—Application has been made for the incorporation of the St. Bartholomew's Hospital and Clinic for Diseases of the Alimentary Canal. The clinic is to be conducted at 215 East 42nd Street. The plans of the organization are to extend the work established by Bishop Greer when he was rector of St. Bartholomew's Church.

Traffic Fatalities in Washington.—The records of traffic accidents in New York and Washington were the subject of a recent report by the highways transport committee of the Council of National Defense. The report shows that for the six months ending December 31, 1918, Washington with a population of 450,000 had 82 fatal street accidents, while New York with a population of 6,000,000 reported 679 deaths due to this cause. Had the fatalities in Washington been proportional to those in New York but 42 fatal accidents would have occurred.. If the Washington death rate were extended throughout the United States there would have been 21,221 persons killed while if the New York rate were similarly extended the number would have been 12,450. The report expressed the opinion that with standardized regulations and some simple but necessary precautions taken it should be easy to reduce the traffic accidents in every city and town in the country far below what they are.

The War's Toll of Nurses.—A recent announcement by the American Red Cross states that there are 184 gold stars on the service flag of the American Red Cross Department of Nursing at Washington. The record is still incomplete and when the roll of honor is finally closed it is probable that fully two hundred American women will have laid their lives on the altar of freedom. Death came to these American nurses in many forms; nearly one hundred nurses succumbed to influenza in the training camps of this country; many were victims of the disease when it raged in the war zone; while ministering to the wonded in France others were killed by Hun ruthlessness in airplane raids.

Surgical Supplies for Siberia.—A shipment to Siberia of ambulance bodies and surgical supplies valued at $348,850 has been authorized by the American Red Cross. This step was taken on the recommendation of Major Kendall Emerson of Worcester, Mass., who has just returned from the field reporting that the Red Cross Commission to Siberia is in most urgent need of surgical dressings.

Dr. James B. Parramore of Jacksonville, Fla., has been appointed local examiner for his district under the War Risk Insurance Bureau and the United States Public Health Service.

Lieut. Col. William W. Haskins has been honorably discharged after two years' service as Post Surgeon at the United States Military Academy, West Point, N. Y., and has resumed his practice at his former address, 40 East 41st Street, New York City.

Dr. Emily McLeod of Boston has sailed to join the Serbian Unit of the American Women's Hospitals. She had been assigned to work in Armenia.

Dr. Jacobi's Funeral was held on Monday of this week. After a brief private service at his late home, his body was taken to the Academy of Medicine and placed in Hosack Hall, where a very large number of the physicians of the city had gathered. A quartette from the choir of St. Thomas' Church sang "Abide with Me," "Lead, Kindly Light," and Tennyson's "Crossing the Bar." The funeral orations were pronounced by Dr. Reginald Sayre and Mr. George Haven Putnam, the former speaking of Dr. Jacobi's work as a physician, the latter dwelling upon his civic virtues and deeds, noting especially his patriotism all during the war just ended. The burial, which was private, was in Greenwood Cemetery.

Death of Lord Raleigh.—One of England's greatest physicists, John William Strutt, third Baron Raleigh, died on July 1. He was born on November 12, 1842, and was educated at Trinity College, Cambridge, where he was Senior Wrangler and First Smith Prize man in 1865. One of his most famous achievements was the discovery of argon, which he effected in 1894. He gave his attention more particularly to chemical physics, capillarity, and viscosity, the theory of gases, the flow of liquids, photography, color vision, optics, the wave theory of electric and magnetic problems, sound and hydrodynamics. His peculiar genius lay in a rare combination of mathematical and experimental skill.

Obituary Notes.—Dr. EUGENIE R. ELISCU, a graduate of the Women's Medical College of the New York Infirmary in 1893, died at her home in New York City on July 11, aged 53 years. Dr. Eliscu lectured in various cities for the National Social Hygiene Society and the New York Social Hygiene Society. She was treasurer of the American Pharmaceutical League.

Dr. HENRY T. MANSFIELD of Needham, Mass., a graduate of Harvard Medical School in 1869, died at his home on July 6, aged 81 years. He was formerly assistant paymaster of the United States Navy, stationed at Charleston, S. C. He had resided in Needham since 1874, where he was for many years town physician and chairman of the Board of Health. He was a member of the American Medical Association, the Massachusetts Medical Society, and the Harvard Medical Alumni.

Dr. AMOS J. GIVENS, proprietor of the Stamford Hall Sanatorium, Stamford, Conn., died there of heart disease on July 7, aged 60 years. He was a graduate of the Eclectic Medical College of Cincinnati, Ohio, in 1886, and was formerly connected with the Middletown State Hospital at Middletown, N. Y.

Dr. ELIZABETH R. BUNDY died at the Woman's Hospital at Philadelphia on July 2. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1884. She was assistant professor of anatomy in her alma mater for a number of years, and for sixteen years visiting physician to the Woman's Hospital. She was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. ROBERT MEADE SMITH died on June 23, at his home in Gwynedd Valley, near Norristown, Pa., at the age of 65 years. He was a graduate of the medical department of the University of Pennsylvania, and at one time served as instructor in medicine in his alma mater.

Dr. CHARLES B. HOUGH died at Ambler, Pa., of heart disease while visiting a patient, on July 2, at the age of 64 years. He was graduated from Jefferson Medical College in the class of 1878. He was a member of the Montgomery County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Obituary.

ABRAHAM JACOBI, M.D., LL.D.

NEW YORK.

DR. ABRAHAM JACOBI died suddenly on July 10, at Bolton, Lake George, which had been his summer home for many years. He was born at Hartum, Westphalia, on May 6, 1830. He attended the gymnasium at Minden, and went thence to the University of Greifswald, where he first took up the study of linguistics, but soon dropped that for medicine, which he followed at Bonn and Göttingen, receiving his degree of M.D. from the latter in 1851. Hardly had he obtained this degree when he became identified with the revolutionary movement, was arrested on the charge of high treason, and imprisoned in Berlin and Cologne for two years. Upon his release, being warned that the authorities intended to try him again, he escaped to England, and after a few months there came to this country and began the practice of medicine in New York City in 1853. He gave special attention to the subject of diseases of children, and was called in 1860 to fill the first

chair of pediatrics (in the New York Medical College) established in this country, having previously lectured on the pathology of infants and children at the college of Physicians and Surgeons. He held this chair for four years, and then became professor of the diseases of children at the New York University, and in 1870 was called to fill the chair in the same subject at the College of Physicians and Surgeons, remaining there until 1902, when he was appointed emeritus professor. In 1894 he was invited to the chair of pediatrics at the University of Berlin, but was too loyal an American to accept it.

Dr. Jacobi was a member of many societies, national and local, and had been called to the presidency of most of them. He was president of the New York Pathological Society in 1866, the New York Obstetrical Society in 1868, the Medical Society of the County of New York in 1870-72, the Medical Society of the State of New York in 1882, the New York Academy of Medicine in 1885-89, the American Pediatric Society in 1891 and 1906, the Association of American Physicians in 1896, the American Climatological Association in 1896, and the American Medical Association in 1912. For nearly half a century the German Medical Society of New York held its meetings at his house. He was an honorary member of countless medical societies in America and in almost every country in Europe. The degree of LL.D. was conferred upon him by the University of Michigan in 1898; Columbia, 1900; Yale, 1905; Harvard, 1906; and Jefferson, 1913.

Many hospital appointments, attending and consultant, were held by Dr. Jacobi during his sixty-six years of medical life in New York, and he had also contributed largely to the literature of his profession. Among his important works were: "Dentition and Its Derangements," 1862; "The Raising and Education of Abandoned Children in Europe," 1870; "Infant Diet," 1872, and second edition, 1875; "Diphtheria," 1876; "Treatise on Diphtheria," 1880; "Pathology of the Thymus Gland," 1889; "Therapeutics of Infancy and Childhood," 1896, and later editions in 1898 and 1903; and "Intestinal Diseases," 1909. He wrote articles of great value for many cyclopedias and systems of medicine and for medical periodicals, his last publication being in the MEDICAL RECORD of March 15 of the present year. A collection of all his medical writings up to 1909 was issued that year, in eight volumes, under the title "Collectanea Jacobi." Within a few years after coming to New York, at the request of Dr. Stephen Smith, then one of the editors of the *New York Journal of Medicine*, he began a series of abstracts from German pediatric articles for that journal. In 1868-71 he was co-editor of the *American Journal of Obstetrics and Diseases of Women and Children.*

In 1873 Dr. Jacobi married Dr. Mary Putnam, herself a most learned physician and medical educator. She died in 1906, leaving a daughter, now the wife of Mr. George McAneny of this city. Last summer a fire in Dr. Jacobi's summer home in Lake George imperilled his life, which was saved only by his jumping from a window. He was at the time working on his reminiscences, and almost the entire material for the same, the collection of seventy years, was destroyed. The loss to the history of medicine and to the history of the unrest in Europe of 1848 is incalculable.

Correspondence.

FOR THE REPEAL OF THE NEW YORK STATE NARCOTIC DRUG LAW.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Physicians desiring to indorse the petition to the New York Legislature referred to in the MEDICAL RECORD of July 12, page 12, for the repeal of the law for a narcotic drug commission in this State, can do so by sending a signed letter to this effect to the undersigned.

JOHN P. DAVIN, M.D., Secretary.
117 WEST SEVENTY-SIXTH STREET, NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, June 20, 1919.

The Fellowship of Medicine.—The Wednesday evening social meetings of the Royal Society of Medicine have been exceedingly pleasant and useful functions. Great men have spoken at them, and large gatherings of interested hearers have afterwards discussed the particular topics introduced, as well as every other subject under the sun in an informal way. The series have now come to a close, but it is almost certain that a similar enterprise will be undertaken in the near future by the Society, for they will form an excellent link with general medicine of the activities of the Fellowship of Medicine, which owes so much to the Society.

The Fellowship of Medicine is, in fact, getting out of the emergency stage, and surely will make of London a truly post-graduate center for Europe. Of the aspirations of the Society in this direction I have spoken several times in these letters, while on your side of the Atlantic such prominent British medical men as Sir Arbuthnot Lane and Sir St. Clair Thomson are sure to be popularizing the idea. The practical step has been taken of electing an Anglo-American committee, and the following have been appointed to serve: Brig.-Gen. H. S. Birkett, Maj. W. Byam, Maj. Carrol, Lt.-Col. S. C. Gurney, Maj. J. H. Irwin, Dr. Robert Knox, Dr. Arthur Latham, Dr. G. H. MacLean, Col. C. F. Martin, Maj. C. H. Palmer, Dr. V. E. Sorapure, Col A. M. Whaley, Mr. E. Bradner White, Dr. Leonard Williams, Capt. McNair Wilson; Mr. Philip Franklin, F.R.C.S., Eng., will act as American honorary secretary.

The merging of the Emergency Post-Graduate scheme with the existing post-graduate organization of the metropolis awaits formal completion, and then there will remain a good deal of work to be done. For London presents problems of indubitable difficulty when any question of central organization is under consideration in respect of the great general hospitals. The hospitals are spread over an immensely wide area, both actually and in comparison with the area occupied by the hospitals of Vienna, Paris, and Berlin. If time is not to be wasted in transit from hospital to hospital, the work for the post-graduate students will require to be very carefully arranged. But all the medical schools, hospital authorities and lecturers have shown such a hearty regard for the attempts

to found in London a great international post-graduate center, that success in the future seems assured.

The Case of Perry.—The horrid brutality of the Forest Gate murders has caused them to be widely reported and discussed, and their perpetrator, Henry Perry, is now lying under sentence of death. He made a full confession of the crime to the police on his arrest, but at the trial an unsuccessful plea of insanity was set up in his behalf. Whether or not the prerogative of mercy is exercised the case is likely to be discussed among medical jurisprudents because of the diametrically opposed medical evidence. For the Crown the medical officer of the prison declared that he found no evidence of insanity, or any degree of deficiency in intelligence that should unfit the prisoner to plead; for the defense three well known alienists averred that Perry did not know the nature and quality of his acts—at any rate with sufficient clearness to render him a proper subject for legal punishment. The jury took the view of the medical officer of the prison, which is certainly the view which the public expected they would take, but medical opinion lies rather on the other side. The medical evidence for the Crown was forcible and obviously sincere, but there were points in the man's history and genealogy which if proven would seem almost to justify relegation to an asylum rather than the scaffold.

The difficulty in such cases is certainly accentuated by the system of trial by jury, and yet no one would suggest that the life of a man is, on a system of averages, better protected in any way than by submission of the issues to a judgment of a group of plain and unprejudiced men. Juries, however, though individually composed of just men, are apt to be swayed by crowd opinion, and where a crime is of a very detestable sort, so that uninformed opinion is sure to lean towards condign punishment, the jury, more in touch with the views of the man in the street than with the arguments put forward by experts, may take the course that has general approval. And if the experts, the minutiæ of whose discrimination they cannot follow, are seen themselves to be at variance, the verdict is almost certain to be in accord with the public voice.

Knighthoods for Medical Men.—Among the latest to receive the accolade are six medical men, Professor G. Sims Woodhead, the well known professor of pathology at Cambridge; Professor F. W. Mott, the leading clinical neurologist of the English school, whose admirable work in relation to shell-shock has borne ample fruit; Mr. D'Arcy Power, surgeon to St. Bartholomew's Hospital; Mr. Charters Symonds, vice president of the Royal College of Surgeons of England; Mr. Cuthbert Wallace, and Mr. W. T. Lister.

The Pollution of the Air.—The Advisory Committee on Atmospheric Pollution, appointed by the British Meteorological Office, have issued a report —the fourth of the series—dealing with atmospheric pollution as gaged at 24 stations of diverse environment during the year 1917-1918, the term ending with March of the latter year. The amount and character of the deposits are set out with appropriate comment as to the monthly fluctuations at the different stations, and the determining causes. Among the broad lessons of the report is that for various reasons an improvement of the state of the atmosphere has occurred during the winter months, whereas the deposits in the summer months are growing heavier. Dr. Owens, who is responsible for the technical work, has now invented a method by which suspended impurity in the air can be measured continuously, and this advance in technqiue should make future investigation more thorough, and lead to a better understanding of the causes of pollution. The developments foreshadowed should be of great practical assistance in clinical medicine, and it is to be hoped that extended trials at an increased number of stations will be put in hand.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, June 22, 1919.

Wounded Americans in France. — Hostilities ceased seven months ago, but there are still several thousand American soldiers in the military hospitals in France, most of them too ill to stand the journey home. Every transport that sails and every day's delay in their recovery makes these men more homesick. The Hospital Centre at Nantes is one of the largest remaining in France. It contains between 1000 and 1500 patients. The way in which the men pass their time and the efforts put forth to make their lot more comfortable and bearable are typical of those at other places. The Red Cross hut is the center of all entertainment and recreational activities. Of all its variety of features, the one which has maintained the steadiest and greatest popularity is the library. From its records can be gained a fairly good idea of the trend of the minds and thoughts of these less fortunate men of the American Expeditionary Forces. Books on banking, salesmanship, psychology and various other subjects are in the greatest demand. The aim of the library officials is to provide books that will help the men in pursuing interrupted studies.

The hut workers devote many hours daily to visiting bed patients in the wards, distributing books and magazines and various comforts. In the past four weeks the men have received 202,000 cigarettes, 1200 comfort-bags, 1650 pair of socks, 1400 handkerchiefs, 1500 tubes of tooth-paste, and large quantities of fruit, chocolate, tobacco, gum, shaving and toilet articles, slippers, towels and games. The daily output of icecream is now about 500 portions. The canteen serves lemonade, doughnuts, tarts, and cookies.

Belgian Children.—When the armistice was signed and the Belgians at last saw the beaten Germans departing, and realized that they had been able to keep their children alive during the occupation through the generosity of America, they thought the days of disaster were over. But new problems have arisen and it may again be necessary to call upon the outside world for help. The great problem at present is how to maintain the colonies for children throughout the country. It is no longer a question of food, but the question of providing permanent buildings for these chil-

dren. Hundreds of buildings and chateaux, with extensive grounds, were placed at their disposal during the war in order that they might get the children away from the cities and endeavor to quiet their nerves in the country. But the owners of those properties are now returning to their residences in Belgium or must sell them. While the crippled industries are waiting for machinery to replace that which the Germans destroyed or carried away, the women of Belgium are putting their hands to the wheel and commencing to rebuild the nation by strengthening the children and fitting them to handle the new machinery. Work for the children of Belgium has become the most important undertaking of the nation. Children who were born in cellars and lived for months under fire that wrecked their nervous system from the outset; children who were born as their mothers were fleeing from burning Liège, Louvain, Dinant, Tamines, or other towns where the Germans committed outrageous atrocities; children given birth by mothers who had lived for four years as prisoners, or children whose fathers were shot down in the presence of the future mothers —these children are to form the Belgian nation of the future.

Long before the Germans had picked up the property they had stolen, and had been driven from Belgium, the brave women who had remained so long under Prussian oppression realized that these children must compose the future race. Few can know what a tremendous and important undertaking it is to make strong men and women out of these weak specimens of humanity, who were brought into the world under the most horrible circumstances. It behooves America, which has shown every willingness to help in the reconstruction of the Old World, to continue the work started by the Relief Commission under Mr. Hoover, and firstly to support the reconstruction work among the children.

Immediately after the outbreak of hostilities, it was realized that work among the children must be taken up by the Government and everything possible was done to make that work effective for the national good. A committee to centralize work for children of every category was, therefore, organized under the Comité National de Secours et d'Alimentation, forming a section called Aide et Protection aux Oeuvres de l'Enfance. Many of the Belgian women who remained in the country occupied by the enemy, and who naturally tried to help the little ones who could not help themselves, coordinated their efforts in such a manner that no work was unnecessarily duplicated. The result has been that colonies for the scientific care of children have been organized in every part of the country, and there is not a single village from the sea to the German frontier that is not represented in these colonies and the exact condition of whose children is not reported to the municipality and to this central committee. This thoroughness has done much to help in the battle against tuberculosis, which has been so pronounced since the war.

Many of the chateaux occupied for the children's work are for sale and it is hoped they will be bought by those who may continue this work.

Excellent work is being done for weak children at Herent, near Louvain. One hundred and fifty deformed children are being cared for there in a beautiful convent which could be purchased at a reasonable figure. Many operations have been performed on these children, who have weak nerves and undeveloped bones. So far the establishment has been maintained by individual contributions. Some of the most noted professors from the University of Louvain have volunteered their services. Professor Maldagne, who remained in Louvain throughout the war, is now the surgeon-in-charge, and the children are nursed by refugee Sisters.

146 Avenue des Champs Elysées.

OUR LETTER FROM GENEVA.

(From Our Own Correspondent.)

Geneva, June 7, 1919.

Legalized Abortion.—An attempt is being made to legalize crime in German Switzerland. This may be a bold statement but here are the facts. Quite recently (May 23), after a long debate, The Grand Council of Basle adopted, by fifty-five votes against fifty, a proposition offered by a certain Welti, socialist, authorizing abortion to be performed up to the end of the third month of pregnancy, on the condition that both husband and wife were consenting or, in the case of illegitimate unions, with the mother's consent and upon the condition that the abortion be performed by a physician in possession of a Federal diploma. The socialists voted *en bloc* for the proposition, likewise two radical democrats. All the other members of the Council, much to their credit, voted against it.

It is evidently without joy that the old Basle families, rightly proud of their ancient city with its glorious historic past, look forward to the prospect of seeing their city become the great abortion center of Central Europe, the city of pilgrimage for young persons who have been sexually indiscreet, if the law is passed and is entered upon the Penal Code of Basle, where, from then on, abortion will be legal. The proposition must be presented for a second reading at which time it will be definitely voted on, when, it is to be hoped, it may be rejected.

In a personal communication to your correspondent, Dr. A. Labhardt, professor of gynecology at the University of Basle, desires it to be stated that both the Medical Society of Basle and the Gynecological Society of German Switzerland, have voted to take extreme measures for combating the passage of this abominable law, the really fearful consequences of which do not seem to be realized by those who are in favor of it.

Spirochætosis Icterohæmorrhagica.—A subject of considerable interest is that of icterohemorrhagic spirochetosis, which has been very thoroughly studied in France of late, particularly by Martin and Pettit, Cassaigne and Fiessinger, and others, and is now well known clinically on account of the relatively considerable number of cases which have come under observation. In more than 50 per cent. of cases, icterohemorrhagic spirochetosis assumes the aspect of a relapsing infectious icterus. The onset is almost always sudden after an incubation period of from six to ten days. It is characterized by one or several chills, headache, and severe local-

ized pain in the thighs, lumbar region, neck, etc. The temperature ranges from 102° to 104° F., and the pulse is about 100, with a lowering of the blood-pressure. Then for 3 to 5 days the "preicteric phase" occurs with prostration, severe myalgia, occasionally ostealgia; a nervous state made manifest by restlessness with torpor, and frequently the presence of a meningeal syndrome—headache, vomiting, Kernig's sign and stiff-neck. There is hypertension of the cerebrospinal fluid with an increase of the albumin content. There is congestion of the conjunctivæ and ciliary body. Albuminuria completes the clinical picture. The less constant signs are those of a peritoneal syndrome, labial herpes, and cough, with occasionally blood-stained sputum.

Icterus appears on about the fourth to the sixth day of the process, commencing in the conjunctivæ, and having the color of a ripe pomegranate. The feces may or may not be decolorized, but there is no pruritus, the pulse is slow, with a low blood-pressure. Epistaxis or other hemorrhagic manifestations supervene, and as there is no tendency to stop, packing the nasal fossæ must usually be done. The liver is not increased in size, but the spleen may be. There is rarely any dilatation of the heart, the kidneys are usually normal, with icteric urine and temporary albuminuria, but hematuria has not been observed so far.

Anemia with a leucocytosis is marked, and in 10 per cent. of the cases an erythematomacular eruption occurs. When the icterus appears the temperature drops to about 100° F. and the symptoms improve. A urinary crisis ensues toward the fourth to the seventh day and the temperature reaches the normal. This period, which is called the "intermediary phase," lasts four to five days, during which the patient is exhausted, and then the relapse takes place, ending in defervescence in three or four days. Usually there is but one relapse, but two or three have been known to occur in some instances. Convalescence is long, as thersia is frequent, brachycardia possible, and alopecia common. From the viewpoint of prognosis, the mortality in France has so far been 5 per cent.

Swiss Surgical Society.—The sixth annual meeting of the Surgical Society of Switzerland took place on the 5th and 6th of June at Soleure. The program was varied and excellent. Of particular interest was a case reported by Dr. Perret, of facial paralysis treated by end-to-end anastomosis of the hypoglossal and facial nerves. The patient suffered from severe facial neuralgia which was treated by retrogasserian division of the fifth nerve.

Dr. Charles Perrier reported a case of cortical abscesses of the kidney following furunculosis. Renal decortication, followed by gauze packing, was done. The patient developed a spastic intestinal occlusion and a stercoral sinus formed. Recovery took place. Among the many important papers read was one of particular interest by Wildbolz on the urine cutireaction as a biological test of the cure of tuberculosis of the epididymis or as an indication for surgical interference.

Mistaken Diagnosis of Beriberi.—Bobeau states that autopsies on alleged atypical or frustrated cases of beriberi made in the tropics show at times the presence of quite different maladies, as Addison's disease and tuberculous cachexia.—*La Presse Médicale.*

3. The Importance of the Early Detection of Glaucoma and Its Management.—J. A. Kearney points out that the glaucomatous process, if unchecked, leads to certain blindness. When the optic head is found to be excavated, the process is uncurable but may be delayed by conservative and operative treatment judicially applied. Cure is possible in the prodromal attacks and in acute congestive attacks before the optic nerve and retina are injured by the intraocular pressure and therefore the importance of early detection cannot be overestimated. Intraocular tension should be suspected when a patient applies for reading glasses before the age that is usual, or, if wearing reading glasses, he applies for stronger ones at short intervals. It will usually be elicited that some time previously when looking at a light, rainbow colored rings appeared about it, vision being temporarily obscured, and that he had dull frontal headaches. Such prodromal attacks last several hours and later the eye appears to return to normal. If during the attack the eye is closely examined, the tension will be found to be increased, the anterior chamber to be shallower than normal, with faint cloudiness of the cornea and somewhat dilated pupil. Worry, mental emotion, insomnia, a hearty meal, or a drop of atropine solution placed in the conjunctival culdesac during or following a prodromal attack of glaucoma may set up an acute congestive attack, characterized by pain which sometimes becomes intolerable. The pain occurs on one side of the head and extends to the teeth and ear, the face is pallid, and vomiting frequently occurs. Vision is markedly reduced but rarely results in blindness in the first seizure. The tension of the globe is elevated, the ocular conjunctiva congested, the cornea markedly cloudy, preventing an examination of the fundus by the ophthalmoscope. It is insensitive to touch, the anterior chamber is shallower than normal, the iris narrowed irregularly giving an oval shape to the pupil and is inactive to light stimulus, and a greenish reflex is seen in the pupillary space. Untreated prodromal attacks nearly always merge imperceptibly into the chronic inflammatory glaucomatous condition, which supervenes much more quickly when an acute congestive attack is set up in the prodromal stage and remains unchecked. After prodromal and slight acute inflammatory attacks the eye may return to normal, but it never does so after chronic inflammatory glaucoma. The elevated intraocular tension in chronic cases gives the so-called glaucomatous aspect, characterized by a purplish ring of blood vessels surrounding the cornea, shallow anterior chamber, grayish iris, oval and dilated pupil rarely reacting to light. The optic nerve head when it can be viewed by the ophthalmoscope is found to be pale and excavated. There is a history of sinking vision. This stage may pass into absolute glaucoma in which the eye is blind and stony hard and all the objective and subjective symptoms are exaggerated as a result of the degenerative process. In glaucoma simplex there is absence of congestive symptoms and pain and almost without exception both eyes are affected simultaneously. Diagnosis is determined by ophthalmoscopic examination when reports are given of a gradual diminution of vision. The fundus picture reveals an excavated optic disc usually with its choroidal halo and occasionally an arterial pulse. The depth of the excavated disc depends upon the time the condition has existed. The primary type of glaucoma develops without the existence of previous ocular disease; the

secondary type is the sequel to previous disease or injury. Predisposing factors in primary glaucoma are: age—over forty years; heredity—Jews, Egyptians, and Brazilian negroes are most frequently attacked; refraction of eye is hyperopic; unusually small cornea; large crystalline lenses. The disease is more likely to develop in thin and dyspeptic women and is usually associated with bronchitis, heart disease, syphilis, influenza, gout, trigeminal neuralgia, or chronic intoxication. No adequate explanation of the disease has been given and there is no definite line of treatment. Conservative measures employed at the time of the prodromal attack and continuously thereafter may check symptoms. Miotic solution dropped into the culdesac keeps the iris strongly contracted at all times with the lowest strength solution; or weak solutions of eserine salicylate, one-eighth grain to the fluid ounce, or pilocarpine, two grains to the fluid ounce, are usually effective in the beginning, but have to be strengthened later. The miotic treatment, if properly carried out, may prevent loss of vision for years but unceasing attention to the eye and general health will be necessary for the remainder of the patient's life. Should there be progressive reduction of the visual field or a congestive attack, operative measures must be considered. If the intraocular tension is sufficient markedly to reduce the visual field without a congestive attack, or with only a slight congestion, an iridectomy is indicated just as soon as an operator can be reached. If the pain in an acute congestive attack becomes violent a sclerotomy must be done at once, and if an eye surgeon is not at hand the physician is justified in operating. The author has devised a sclerotome for beginners with a stop fifteen millimeters from the tip of a blade which has the lines of a Graefe cataract knife and he gives a careful description of the operation. The keratome with bread knife edges devised by Paul F. Cavanagh is the instrument of choice in the iridectomy operation. In chronic inflammatory glaucoma the iris is usually atrophic and nearly always welded in the spaces of Fontana, and the degenerated membrane has to be picked out piecemeal. The author points out that the subconjunctival fistulizing operations, like those of LaGrange and Elliot and their modifications, carry with them some danger of late infection. In five patients with chronic inflammatory glaucoma who refused the major fistulizing operations, the author was able to keep them comfortable by instilling eserine and dionin in the culdesacs at stated times following a hot water lavage of the eyes, occasionally a soporific of codeine sulphate by the mouth in very small doses, and operatively a succession of modified posterior sclerotomies—more than four rarely being found necessary. The reduction of vision in the series varied but little from that following the usual major operations.

4. Exfoliative Dermatitis Due to Arsphenamin: Report of a Fatal Case.—Joseph R. Latham reports a case which occurred in the base hospital at Camp Jackson, in which a fatal result followed the intravenous administration of 0.8 gm. of arsphenamin. The case was one of four which occurred at the hospital but was the only one to end fatally. In its general features it bears the stamp of arsenical intoxication, the clinical diagnosis being confirmed by abundant laboratory data. The patient, aged 27, was in excellent physical condition and gave no sign or symptom of syphilis; he denied venereal infection but gave a positive Wassermann. He was given 0.4 gm. of arsphenamin, the reaction being so marked that he was in hospital for a week. He was then sent to duty but a peculiar keratoid condition of the face and neck was noted. A week later he received a second dose with no apparent reaction; ten days subsequently, however, he was again admitted to hospital complaining that the skin of face and neck was hard and red and knobby to the touch, and was burning and tingling. Four days after admission the skin began to exfoliate, the condition becoming steadily deeper and more extensive and reaching its maximum about thirty days after the first dose of arsephenamin. There was fever, and pronounced leucocytosis followed by toxic symptoms and progressive physical and mental deterioration. Death occurred on the thirty-eighth day following the first dose of arsphenamin. In this case therefore a fatality followed a therapeutic dose of arsphenamin which was the equivalent of less than 3 grains of metallic arsenic. Diarrhea and vomiting were absent during all stages of the intoxication. Nephritis was not a marked feature at any time, and appeared only at the end. There was apparently a decided affinity of the poison for the skin or for the trophic nerves supplying it, and from first to last all the toxic symptoms observed may logically be ascribed to impairment of skin function. Arsenic was persistently present in the urine, which was remarkable in the absence of accompanying renal inflammation. There was a high leucocytosis and eosinophilia, the latter related closely to the patient's resistance. The height of the leucocytosis followed that of the fever. Arsenic was found at necropsy in every tissue in which it was sought.

1. A Post-Graduate Lecture on Mental Disorders Associated With Old Age.—Sir George H. Savage, discussing the lines of decay, refers to Oliver Wendell Holmes' reference on dissolution, but points out that the human body dissolves in parts and not along the lines of the "old shay" which was so marvelously built that every part of it would just last one hundred years, when it dissolved and disappeared. He also points out the importance of the hereditary quality of old age and of the diseases of old age and that devolution is not as regular as evolution. It is of importance to recognize that what might be called the most essential function or element of mind—memory—is one of the first to suffer. A morbid loss of memory may prove of considerable importance from a medico legal point of view, as in the case cited of the man who had four sons and made a will leaving his money to all four, although three of them were already dead. The effects of mental denudation are illustrated also in the case of the father, who received his prodigal daughter with open arms, only to turn against her again later and cut her out of his will. Or in the case of the old man of 74, who after living happily enough with his wife for forty years and more, began to threaten her life on account of an incident which had occurred forty years previously and which he had forgiven at the time. Other cases occur in which a man's memory may be extremely bad and his will capacity quite good. In giving a certificate as to testamentary capacity, it is not necessary always that the memory should be good. On the other hand, the loss of memory may be only temporary. In other cases, recent happenings may be forgotten while older experiences are vividly recalled. The author cites several

cases in illustration and shows that loss of memory with denudation which is supposed to be associated with loss of brain function, may be very dangerous. He then turns his attention to another feature, that of loss of control, reminding us that years ago Hughlings Jackson pointed out that there was layer upon layer of the nervous system, that the last developed was the highest in function, the great controller, and that by the removal of something, power seemed to be increased; that is, control being removed, the next function or part of the brain reacted to stimuli much too vigorously, so that with loss of control there was often exaggerated action. One of the most troublesome of the minor symptoms to which this loss of control leads is the restlessness of old age; *e. g.*, the old man of from 60 to 80 with grandiose ideas who wants to marry or is for ever starting new schemes. Another feature is the sleeplessness of old age. The hysterical emotional condition is another serious complication which not only lays the aged open to undue influence by others, but leads to many sexual complications and indecencies. Again, there are the cases of mental depression or senile melancholia, obscessed with imaginary bodily or mental troubles; and the cases of what the author calls the "saturated solution of grief," as, for instance, the bishop who feels that he was never fit to be a bishop, the old doctor who thinks he has aneurysm or cancer, the business man who imagines he is ruined. "Every senile melancholic is a suicidal person" is an axiom of the author's, which is particularly true of the mercantile man who believes he is ruined. Finally, the author takes up the hallucination group, in which there is pure sensory disorder. In such cases the same symptoms occur both with evolution and dissolution; the youth on the road to dementia precox suffers from hallucinations of smell and of sight very similar to those met with in the aged, and here the author points out that the organ of smell, though a lower one, is very highly organized and is closely associated with our whole mental stability and mental growth. A study of the cases cited, as the author states, teaches the importance of learning one's limitations, and not only one's own but normal limitations. He points out, however, that lots of people, though old, are useful, and that a person who has had energy enough to live to 80, probably has a reserve energy which can be called upon when required. He would therefore consider a patient who broke down at the age of 60 more hopefully than one who broke down mentally at 16. He adds that we must remember that many of the best, brightest, and most intellectual people die "at the top."

1. The Physical State of the Blood Serum in Relation to Its Agglutinin and Antibody Content: the Effect of Friction and Pressure.—C. J. Bond states that he noticed two years ago that if two separate drops of a blood serum containing hemagglutinin were allowed to dry on a slide and if one of the drops was dissolved in normal saline solution without friction, while the other was rubbed with a glass rod, the drop which had undergone solution without friction retained its full hemagglutinative capacity, but the drop which had been rubbed failed to agglutinate the red cells or did so very feebly. Starting from this point the author has investigated the effect of combined friction and pressure on certain blood serums of known hemagglutinative capacity. These observations seem to show that by submitting blood serum and other body fluids to a mechanical process, which includes friction combined with pressure, physical changes can be brought about in these fluids which throw some light on the condition in which hemagglutinins, bacterial agglutinins, complement, complement deviating substances, and antibodies exist in the blood serum. They suggest that the blood serum and body fluids, the secretions and excretions, form a graded series with the blood serum at one end, and the excretions, such as the urine, at the other. The hemagglutinins seem to be present for the most part in a free state in the blood serum, and in a more or less combined form in the transudates and exudates, while in excretions like the urine, the hemagglutinins when liberated and recovered in the free state are found to have lost their specific character. This is shown by testing the agglutinative capacity of the fractional series of liquors and sediments to the same varieties of washed red cells. Not only do the hemagglutinins show marked differences of composition in the different liquors and sediments, but they also vary according to the extent to which the fluid has been submitted to the mechanical fractional process. This is also true of the bacterial agglutinins contained in blood serum, and it has been found possible by these means considerably to increase the agglutinating titre of a blood serum to a given organism while retaining at the same time the specificity of the reaction. This suggests that it may be possible to raise the agglutinating capacity of a serum by a mechanical process *in vitro* for therapeutic purposes. These observations also show that the complement deviating factor in positive syphilitic serums passes over along with the hemagglutinins and bacterial agglutinins into the liquor, and is not thrown down with the sediment. By taking as the standard of vitality emigration from the clot, capacity to elaborate iodophil substances and phagocytic activity, the author was able to test the relative leucotoxicity of the liquors and sediments obtained by the fractional grinding treatment of blood serums and body fluids. Of 80 different blood serums from different individuals 13 were very toxic, 25 were slightly toxic, and 42 were non-toxic to the leucocytes of the author himself. In practically all cases the sediment was markedly toxic, while the liquor might or might not be toxic to the same leucocytes. In a few cases the liquor obtained by grinding a toxic serum became non-toxic to the same cells. Bond points out that the problem of the leucotoxicity of different blood serums has a practical bearing on blood transfusion and vaccine and serum therapy. He is inclined to regard horse serum as markedly toxic to the leucocytes of certain individuals, a fact which may have some reference to the varying liability to serum sickness shown by different individuals. He adds that, although fully aware of the incomplete character of these observations, he thinks they show the great importance of certain physical factors—such as friction and pressure—in relation to the antibody content of the blood serum and other body fluids and is hopeful that the treatment of these fluids by a mechanical process which combines friction and pressure may open up a road for the further investigation of the biochemistry of the blood serum.

6. Early Bone Grafting in Wounds.—R. Atkinson Stoney points out that since the beginning of the war the operation of bone-grafting which was just coming into fashion, has received a great impetus, and a great advance has been made in this branch of repar-

ative surgery. More especially is this true of wounds of the face involving loss of substance of the lower jaw, where really remarkable results have been obtained. In spite of the very large field of usefulness for this operation in gunshot wounds of the limbs causing extensive loss of bone, the results have been more or less disappointing and the number of cases treated and recorded is not so large as might have been expected. The explanation is simple. A wound of the limbs, either upper or lower, involving the destruction and loss of a considerable area of bone is liable also to cause so much destruction of the soft tissues and to be followed by such severe infection, that amputation has frequently to be resorted to. Even if amputation is not performed, the period of infection is prolonged, during which time, and, indeed, for several months after all suppuration has ceased and the wound has closed, it is generally admitted that attempts at bone-grafting are worse than useless. By the time one of these cases has remained treated for some months, so that there is a reasonable hope that fresh infection will not be started by reopening the tissues, considerable deformity is likely to have occurred, and scar tissue has formed so extensively in the neighborhood that a bone-graft has little chance of either relieving the deformity or living in the poorly nourished scar tissue. In the case of the lower jaw, these difficulties are not so pronounced, deformity can be prevented by the use of interdental splints and other modern appliances, the tissues are looser and the blood supply more abundant; the loss of bone is usually less, and, therefore, a smaller graft can be used, with consequently less probability of failure. Stoney in view of the danger of restarting infection in the tissues by an operation for bone-grafting even six months after the wound has healed, suggests that it may be possible to perform bone-grafting in recent wounds and cites a case in which this was done and which was partially successful. Indeed the operation not only did no harm, but may even be said to have done a considerable amount of good.

2. Typhoid Spine.—Sir William Osler describes a case of typhoid spine which had resisted treatment for two years and which was cured after ten minutes' treatment. It was an aggravated case, paralyzed for nearly two years, unable to move body or legs and yet the patient walked after ten minutes' treatment. In showing a case at the Johns Hopkins Medical Society in 1901, Osler dwelt upon the following features as indicating the functional character of the condition. First, a state of neurasthenia with vasomotor changes, and in a few cases the definite stigmata of hysteria. Secondly, stiffness of the back, persisting for weeks and months, is associated with pain, sometimes of an agonizing character, on movement. Thirdly, pain on pressure over certain spinal processes. Fourthly, a negative local examination, with the absence of fever. And lastly, in many cases, prompt recovery, with the use of the Paquelin cautery, and measures directed to the neurotic condition. Osler thinks that perhaps the most interesting case on record is the study by Dr. Leonard Ely, of New York, of his own attack, published in the MEDICAL RECORD, September 20, 1902. He says that while one hesitates to suggest the existence of hysteria in a professional brother, one may say, at any rate, that the condition simulated it, and Ely confesses to have been "considered hysterical by his nurses." The professional baseball pitcher, whose protracted case is reported by Carnett, the cases of Lovett and Withington and Taylor's case had hysterical features combined with organic changes. Of the local features, pain the back is the most constant, and it may be of extraordinary severity, so that the patient screams on the slightest movement. It comes on in paroxysms and is aggravated by the slightest jar or at any attempt to move. The pain may be of a definite nerve-root character, extending round one or both sides, or it may pass down one or both legs. Tenderness on pressure is present over the spinal processes of varying numbers, sometimes limited in the lower dorsal and lumbar regions. Rigidity of the back is a constant feature; the patients are unable to stoop, and have a difficulty in raising themselves to the sitting posture. If, as some orthopedic surgeons hold, a rigid back indicates organic disease, all of these patients had it. Chronic contraction of the muscles has been present in a number of instances. It may be nothing more than the fine tremor on attempting moving the legs; but there is one type of muscular contraction in these cases that is of great importance, as Osler thinks it is an unerring stigma of hysteria. The rhythmic contraction of the abdominal muscles, noted by Ely in his own case, and present in two of Carnett's cases, is referred to. Inability to use the legs is present in severe cases, but there is no actual paralysis, no wasting, and the features are quite unlike post-typhoid paraplegia from myelitis or from neuritis. Reflexes are increased, but not changed in type. Disturbance of sensation in the form of hyperesthesia are common, particularly in the back. Anesthesia may be present. The last and important point is the evidence which exists in some cases for disease of the spine. This is of two forms: Kyphosis has been present, and of a type that could only occur from positive disease of the bone. Upon one remarkable feature all writers dwell. Unlike ordinary typhoid periostitis the spondylitis rarely, if ever, goes on to suppuration. When present the lesion must differ essentially from that which we see in the long bones and the ribs. Typhoid bacilli have been frequently found in the bone marrow of the vertebræ and there is no inherent reason why similar inflammatory changes should not be produced as in other bones. We know, indeed, from the presence of the kyphosis and from the *x*-ray picture that such changes do occur. Why they are not seen more often is, Osler believes, because they are not always present, and because we must recognize functional variety, which has its counterpart in certain forms of hysterical and railway spine.

Berliner klinische Wochenschrift.

April 7, 1919.

Acute Polymyositis and Trichinosis.—N. Dragoewa states that cases of trichinosis have become more frequent in Germany since alimentation has become less eclectic. The writer has had the opportunity of observing both trichinosis and polymyositis and was able to note a marked clinical resemblance between the two morbid processes. Typhoid fever may also resemble certain forms of trichinosis. There are even borderline cases where the differential diagnosis between polymyositis and trichinosis is very difficult to make. Besides microscopical examination of bits of muscle, blood examination is of the highest importance. The writer found an average eosinophilia of 30 per cent. in trichinosis, this percentage rising or dropping according to the fluctuations occurring in the disease. On the other hand, in polymyositis the eosinophilia is normal but an accidental eosinophilia may occur (as high as 16 per cent. in a case of pseudo-trichinosis), so that repeated examinations are required. In the case of diagnosis of trichinosis a high and constant eosinophilia must be present.

The Spirillicidal Action of Neosalvarsan on Syphilitic Lesions.—R. Müller and F. Gross have searched for the spirochetæ in luetic lesions after injection of neosalvarsan. Their results may be summed up as follows: In the vast majority of cases of chancre with a positive Wassermann a dose of thirty centigrams of neosalvarsan is followed by a disappearance of the spirochetæ within fifteen hours. In cases of chancre with a negative Wassermann, after a dose of thirty centigrams of

neosalvarsan the spirochetæ are still present sixteen to twenty hours later, although often diminished in numbers. There is, therefore, a sort of antithesis between the curability of syphilis according to its stage and the sensibility of the spirocheta to the drug. This paradox, that the spirocheta is all the less resistant the more it is acclimated to the organism, lead the writers to make some theoretical remarks. The exhibition of Hg. is not followed by the same local reactions on the spirocheta as is the case with neosalvarsan.

Deutsche medizinische Wochenschrift.

April 3, 1919.

The Physiology of Alimentation: Results Obtained During the War.—A. Loewy and H. Strauss show that the fundamental notions of the physiology of alimentation have been confirmed during the war. Some new data have been added. From the viewpoint of calorimetry the minimum of 1600 calories per day and the minimum ration of 2400 calories for laborers has been verified. The ration of albumins, which according to Voit has 198 gram. as a minimum, can be diminished to about 70 gram. or 66 per cent., a quantity recognized as sufficient by most writers. This figure is variable according as to whether the total number of calories is normal, insufficient or in excess. The war has shown that prolonged denutrition ends in a condition of nitrogen equilibrium after the expiration of a certain lapse of time, during which the body weight progressively decreases. Thus a ration of from 1300-1800 calories (comprising 40 grams albuminoid) is sufficient for subjects weighing from 40 to 48.5 kilograms, while a person of 51 kilograms will not compensate his waste products with this same ration. This phase of denutrition is, therefore, characterized by a decrease in the phenomena of disassimilation. Below the above mentioned ration a rapid loss of weight is noted with phenomenon of nervous deficit, viz., great weakness, irritability, delirium and hallucinations. During the war fats have been replaced by carbohydrates but as the latter were insufficient in quantity, it has been impossible to determine the disturbances resulting exclusively from an insufficiency of fats. Nevertheless, it has been established that the absence of fats causes the food to be less satisfying. Fat (or its lipoids) still seems to be particularly efficacious in combating the edemas due to hunger. The war has likewise shown that the organism can become accustomed to foods which are absorbed with difficulty, this resulting in a better utilization of these foodstuffs.

The Solidity of Nerve Sutures and Nerve Cicatrices.—A. Bethe carried out experiments on elongation of sutured nerves and on normal nerve trunks. As a practical result in man the writer believes that a sutured sciatic nerve can stand the weight of twenty pounds a week after suture and a weight of sixty-six pounds at the end of two weeks if the weight is not applied too long. In considerable nerve defects it is better to resort to homo- or autotransplantation than to simple suture preceded by elongation of the nerve trunk. In point of fact an elongation of short duration, such as is done during operation, is not sufficient to overcome the elasticity of the nerve, so that the nerve will pull on the suture until rupture takes place.

Wiener medizinische Wochenschrift.

March 29, 1919.

General Biology; a Subject to Be Taught in Medical Instruction.—L. Lohner advises replacing the courses on botany and zoology by teaching more adapted to the needs of medical instruction. In order to form "a biological thinker" the student must be used to develop synthetic views on physiology, ecology, and genetics. Such teaching should comprise extensive experimental work.

Wiener medizinische Wochenschrift.

April 5, 1919.

The Advantages of Gauze Plugging after Tonsillectomy.—K. Koflers advises plugging between the two pillars of the velum palatinum. Iodoform gauze should be employed and left *in situ* for twenty-four hours or two days. The advantages are: (1) The prevention of secondary hemorrhage; (2) the preservation of the normal shape of the buccal cavity, since, the author suggests, the pillars of the tonsillar bed do not become adherent to each other, a fact which is particularly to be desired in the case of singers.

Influenza and Tuberculosis.—E. Nobel recalls that various writers have observed that the cutireaction disappears during influenza (just as it does in measles) and have supposed from this fact that there is an aggravation of a tuberculosis often produced by the grippe. Contrary to the experience of these observers, Nobel has never noted a disappearance of the cutireaction during influenza.

The Psychology and Pathology of the Military Aviator.—H. von Schroeter makes some general remarks on the subject and points out that aviation does not appear to exercise any bad influence on the general health and even in certain nervous affections it may have a fortunate effect. For example, the writer has observed a case of Basedow's disease which was distinctly ameliorated by aviation. In the examination for aptitude in aviation it is unnecessary to exact a great sensibility of the labyrinthine apparatus; it is much more important that both labyrinths should be equally perfect.

Correspondenz-Blatt für Schweizer Aerzte.

April 12, 1919.

Epithelial Metaplasia in Influenza.—Askanazy refers to the ability of anatomists to recognize influenza at autopsy with complete disregard to the presence of specific organisms or the clinical history. Of the 320 autopsies made at the Geneva Pathological Institute the monotony was almost wearisome. A deep red or brown red tracheobronchitis, hemorrhagic bronchopneumonia and vasomotor paralyses of blood vessels of all kinds were almost constantly present. Other phenomena outside the thorax were extremely common but did not possess clinical significance as waxy degeneration of the abdominal muscles, cloudy swelling of the large glands and enteritis. Upon this background many other phenomena were off and on present so that the total picture could be very complex. Some of these possess special interest, despite the fact that they were often missed, for they might serve to explain certain features of the disease, as the manner in which it strikes down the young and strong who should resist germ activities. Epithelial metaplasia is a much discussed subject which enters into very diverse disease pictures. In influenza the stratified epithelium of the deeper air passages has been seen to proliferate in a manner which suggests some stimulation of embryonal elements *in situ*. Hence in addition to the desquamation and expulsion of old epithelia we have a new formation *in situ* of epithelial cells. The author does not even suggest that this process could be regenerative in character, probably because it is not necessarily preceded by loss of epithelium. He does discuss the possibility of a defense reaction and securing of immunity by preventing the further invasion of bacteria. According to this conception, Askanazy says, it would be the failure of metaplasia in a given individual irrespective of the degree of natural vigor which would render him susceptible to influenza pneumonia.

Influenza and Croup.—Coray referring to the Fall epidemic of grippe and its augmented mortality in children introduces the conception of a series of croup-like affections as follows: Croup as a complication of ordinary laryngotracheitis, croup in association with pneumonia and finally accidental infection with laryngeal diphtheria. Of the first type there were 10 patients all of whom recovered and 8 without intubation or tracheotomy. Of the second type were 6 cases all but one fatal and of the third 2 cases both fatal. In all six fatalities the indicated surgical treatment was used. These cases have to be differentiated from ordinary croup and simple diphtheria, which is no easy matter.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Eleventh Triennial Session, Held in Atlantic City, June 16 and 17, 1919.

(Special Report to the MEDICAL RECORD.)

First Day—Monday, June 16.

THE PRESIDENT, DR. SIMON FLEXNER OF NEW YORK, IN THE CHAIR.

The Surgical Aspects of Reconstruction.—Dr. JOHN M. T. FINNEY of Baltimore delivered this address in which he said that the old adage "disease and remedy are found together" was never more true than it was to-day. Problems and difficulties abounded; so did solutions. Surgical Reconstruction, to deal with it in its broadest sense came under three main heads: (1) prophylaxis, (2) plastic and reconstruction measures, and (3) prosthesis. Under prophylaxis was included (*a*) a general consideration of the means devised and employed throughout the A. E. F., more especially in the advance combat areas, for the purpose of preventing disease and deformities, that when allowed to occur or progress, might ultimately make necessary the use of reconstructive measures, and (*b*) the primary mechanical and operative technique employed to prevent, or to limit, the necessity for subsequent surgical procedures. Two classes of cases would in the future be noted, namely, the unfortunate class known as "unpreventable deformities," the irreducible minimum, that, owing to the nature of the injury, loss of substance, etc., would remain as an unavoidable consequence of war; and the "preventable deformities" in which the preventive methods must rather be applied at the source than later. Such cases included deformities such as malunited fractures, osteomyelitis from neglected infections, paralyses from divided nerves (possibly due to unwise débridement), contractures from scar tissue, and the like. This aspect of the question belonged more properly to the surgeon, while the management of the later stages was the province of the orthopedic surgeon. At the outset it should be said that it was the group spirit—the splendid spirit of intelligent co-operation that actuated all those engaged in the different departments of the work—that made possible the development of the team work, the effectiveness of which had been testified to by the generally excellent condition in which our wounded soldiers had arrived from overseas. Of great importance as contributing to the general efficiency might be mentioned, among other features of the organization, (1) standardization of material and methods, (2) radical control of patients, (3) expert supervision of the surgical work of well trained consultants. In order to make all these effective to the highest degree, adequate authority for the enforcement of the necessary provisions was essential. Too much emphasis could not be placed upon the important part played in modern warfare by transportation, upon the ability of the ambulance service to deliver the wounded promptly and in good condition to the hospitals further in the rear depended in large measure the particular nature of the problem presented to the surgeon. If the case arrived promptly, that was within twelve hours, it was a question of dealing with the special form of trauma presented; but if later than this, roughly speaking, no matter what the nature of the injury, the problem of infection was paramount to everything else. The attitude of the people in general and the medical profession in particular toward the crippled and deformed at different periods of the world's history made an interesting study. From prehistoric times down to the 16th Century the fate of the disabled and deformed was indeed a hard one. In Christianity the germ of a better destiny for this class of unfortunates had its origin. At the beginning of the history primitive society regarded the cripple as an outcast, doomed to wander in the wilderness, to die of exposure and want, or to be sacrificed to expiate the wrath of the gods. While the attitude of society toward the cripple changed with the advent of Christianity, the new influence was not profound. Gradually since the 16th Century two principles were developed for dealing with this class of unfortunates, namely, pensions and institutionalism. These two principles in one form or another were finally adopted by all civilized nations. According to the unanimous testimony of those affected, the greatest handicap of the disabled was not the loss of limb or other disability, but the weight of public opinion. The record of the great war just over undoubtedly marked a new era in the provision made for the welfare of the disabled soldier. It might be said to have actually begun with the establishment in Lyons, France, by the Mayor of that City, the first training schools for invalid soldiers, although sporadic attempts of a similar nature had been made in Belgium, Russia, Great Britain, and France. This movement spread rapidly through all the belligerent countries and was now generally accepted. Though under strict interpretation of rehabilitation and reconstruction a consideration of preventive measures might seem out of place, still, here as elsewhere, prevention was better than cure. The prime object for which the military surgeon was striving was twofold: (1) To reduce to a minimum, or reduce altogether, the development in the soldier, whether wounded or not, of those conditions which owing to resulting deformity and disability would make reconstruction necessary; (2) to return every disabled soldier to the line in the shortest possible time. To this end surgical aid in the advanced areas should be reduced to the minimum and should have as its aim to ward off deadly complications, to protect the wounded from infection, and to insure rapid transportation to a well conducted hospital. The speaker described how it had come about that trench foot, which was due to cold, plus wet, plus dirt and infection, could be prevented, and through this discovery large numbers of partial or complete amputations had been avoided. It was recognized, furthermore, that the proper splinting of fractures, compound or simple, and of joint injuries, must be provided for at the earliest possible moment after injury, if additional trauma and laceration of tissue, hemorrhage, shock, and infection, and in many cases amputations, were to be prevented. This resulted in the standardization of splints. Turning then to venereal diseases the speaker recalled that in most past wars venereal diseases had played a large part in the loss of man power and efficiency. It was worthy of remark that this particular war problem was dealt with in characteristically American fashion, and in line with ideals and established theories held and practised in the United States; and at first in the face of determined opposition on the part of the French. The basis of the American plan was educational, discouragement in the use of all forms of intoxicants, repression of all forms of prostitution, the infliction of adequate punishment on all those contracting venereal disease, the compulsory prophylaxis, and the use of all available social, moral, and religious influences that might be of any aid in keeping the men straight. The end results of this method of handling an extremely difficult and complex situation had been most gratifying both in improved morale and in salvage of man power for the Army. The speaker outlined the work that each of the highly specialized departments of surgery had contributed toward the general result for which all were striving. Special attention being called to the establishment of an experimental surgical laboratory operating in cooperation with the Central Laboratory, A. E. F., where problems affecting surgical procedure could be worked out Especially valuable were the courses offered in blood transfusion and the physiology and treatment of shock. Under prophylaxis was also considered the practical technical procedures made use of by surgeons in their operative work—débridement, primary suture, delayed primary suture, the organization of surgical teams, *x*-ray teams, and teams for postoperative splinting. The special management of amputations, chest wounds, and maxillo-facial injuries, and systematic antiseptic measures had contributed largely to diminish the need of reconstructive work.

In the domain of neurosurgery the débridement of the injured brain tissue by suction was a distinct contribution. The careful search for and immediate suture of the larger peripheral nerves at the primary operation was distinctly advantageous, for if it was not always followed by regeneration, it at least prevented the retraction and shortening which were usually found so troublesome in late operations. This latter class of operations, in order to obtain the best results, necessitated a most careful and painstaking dissention with an exact anastomosis, to be followed by proper splinting and carefully directed electro-mechanotherapy. Further improvement might be expected from re-education. Attention was also directed to the invaluable aid rendered in war by the *x*-ray. It had been possible by means of *x*-ray camions and extra teams of skilled operators to supply fairly satisfactorily the demands from the hospitals in the combat areas, so that even in rush times the services of an *x*-ray expert were usually available. After discussing various phases of reeducation and occupation for the disabled, the speaker summed up by stating that the purpose in the care of the American soldier was to tend him from the clearing station to the last hospital better than wounded soldier had yet been tended. In special hospitals, orthopedic, phthisic, neurasthenic, we should give him back functional ability, solidity of nerve, or lung. The flesh torn away, the lost spirit, the broken ear drum, the destroyed nerve, it was true we could not give, but we could so recreate and fortify the rest of him that he should leave the hospital ready for a new career. He would be prepared to become a workman with pride in his work, a stake in the country, and the consciousness that, handicapped though he might be, he ran the race level with his fellows, and was by that so much the better man than they. In closing, Dr. Finney urged the practical application to industrial conditions of the experience in surgery gained in the war.

The Neurological Aspects of Reconstruction.—Dr. HARVEY CUSHING of Boston delivered this address. He stated that he could best bring out the point he wished to make by citing a concrete instance. A short time ago he received a visit in his office from two discharged soldiers. The first of these, whom he would designate as Private "L", was the victim of an air raid and had undergone amputation of both legs at the thighs. He had been fitted with artificial limbs, had finally received his discharge after having been graded in the 100 per cent. disability class, and would undoubtedly receive his pension of $57.00 a month. He was a student at the Institute of Technology and had a bright future. The second man, whom he would call "A", received a head wound with loss of consciousness. He was operated on at a field hospital twelve hours later by the chief officer of one of the neurosurgical teams. A detailed record of his case was kept illustrating how carefully observations were made by the neurosurgical teams. These records gave a complete description of his cranial and other wounds and the neurological findings. He was recorded as having aphasia, agraphia, and homonymous hemianopsia. He was removed from one place to another until he finally reached Brest, and was later sent to New York. He was then sent to a base hospital from which he was discarged on December 7 with orders to report for duty. He was found wandering about the streets of his home town without any idea of where he was. He was taken to a local army hospital where he remained four months, during which time efforts were made to reeducate him. He had formerly been a bookkeeper and accountant and was assigned to a class to learn arithmetic, but he became confused and unable to grasp the instruction. He was finally discharged and a disability of 90 per cent. granted him, with a pension of $27.00 a month. He was about the type of an early Jacksonian epileptic, there being a definite slowing of all his mental processes. The status of both of these individuals was open to revision. The soldier who had been subjected to operative treatment received the reward due to a soldier without legs, while the soldier who, to outward appearances was unharmed, but who suffered a residual defect in his cranial processes and had really suffered the greater disability, did not receive a reward commensurate with his injury. The word "reconstruction," like "conservation," appeared to be in danger of being overworked; we seemed to forget that it meant simply later treatment. It referred only to what had been attempted by every other hospital. Occupational therapy was continued in many hospitals and the process was the same in each instance. He had some misgivings lest they might meet with the same defects in their results as were met with in the civil hospitals, especially in the more difficult by-paths of medicine as represented by the psychological cases. Psychological patients and wounded soldiers did not like to go to school in a hospital nor to be ordered into the shops, and in order to keep them a well organized system of entertainment was necessary. The profession as a whole knew less in general about the nervous system than about any other part of the body. The psychiatrists, neurologists, and neurosurgeons of the country were a small minority and their voice had not been listened to. Sane minds were in the long run more essential than sound bodies. The importance of the latter was recognized, yet the stress of life fell heaviest on the central nervous system, and in times of war this strain was increased. When it came to the examinations made by the draft boards the mistake was made of centering attention on eyes, ears, and inguinal rings, and of disregarding the condition of the nervous system. As a result there was a startling number of men with psychoneuroses in the early part of the war. These settled in the hospitals and formed a most difficult class to treat. An effort was then made by the draft boards to comb out the neuropathics, but in spite of this many were left who developed neuroses in the camps and later in the field. It was decided in 1918 to place injuries of the nervous system under a Department of Neurosurgery. Excellent neurosurgical schools were established and a survey was made of peripheral as well as central nerve injuries. It was found from figures compiled by the French that 25 per cent. of disabilities represented neurological problems, and that wounds of the head represented 16 per cent. of all wounds. Cranial wounds did not stand transportation well and required daily observation. Dr. Cushing described the method of keeping clinical records and of forwarding such records from one hospital to another with the patients. When the Division of Neurosurgery was established this system was adopted. The registration of the wounded and their evacuation in an army hospital no less than in a civil hospital was important, and the data collected by a well trained officer might be of value as a basis of study. There were many difficulties, however, and a good follow-up system was impractical. Even where cards were made out and sent with the patient they rarely reached their destination. The surgeon, therefore, got little that was of value in the advancement of surgical knowledge. There was a tremendous number of repairs of nerve injuries. Of these records had been kept as far as possible, but he did not know that they would have more than historical interest, as they would likely not be applicable to future conditions, since the next war would probably be fought in the air, and what was now called a forward would then be called a base hospital. Colonel Salmon at the ports of debarkation tabulated all the neurospinal cases and at the port of entry there was a medical officer to distribute these cases to the proper hospital for treatment. Some had been sent to Cape May and some to Fort Sheridan, but one could not reduplicate superior ability, and the attempt had been on the whole a failure, in that all the men had not been placed where first class ability to treat them was available. This work should be done on a state and national scale and through inter-departmental co-operation. In this way many cases of different types could be brought together and the experienced medical officers of the army could give them their undistracted attention. The manner of distribution made it impossible to keep the men as long as they should be kept, and then, too, many medical officers were desirous of withdrawing from the service. So far as these neurological cases were concerned it was not too late to segregate them. Under the War Risk Insurance they could be gathered

together and the work could be carried out, at least in so far as the purposes were concerned for which that Bureau was established. The lessons learned from the experience and mistakes of this group during and after the war might well be applied to the treatment of industrial injuries. The people and the nation had been aroused by the experiences of the war and private and governmental agencies would be more ready than before to extend activities of all sorts for the public welfare than before the war. In the meantime the Division in charge of neurological cases was falling far short of its opportunities. The plan of sending a neurological case to a hospital near his home was a mistake. Parents were anxious to take the man home as soon as possible and he then fell into the hands of the family doctor who had neither the training nor the equipment to care for cases of this kind. Thus it would be seen that the man who had sustained a cerebral injury was justified in asking whether his country was according to him as good treatment as it was to the man whose legs had been amputated. Every effort should be made to rehabilitate the soldier who was suffering from a cerebral injury during the first enthusiasm of reconstruction for the time would come when the country would tire of its cripples and these cases would still remain unfit and unable to readjust themselves to their social environment.

The Work of Physical Reconstruction as It Concerns Orthopedic Surgery.—Dr. Joel E. Goldthwait of Boston, formerly Colonel Medical Corps, United States Army, and Senior Consultant, Orthopedic Surgery, A. E. F., delivered this address. He said, in part, that what orthopedic surgery primarily stood for was the preservation of function in parts which were injured or diseased or in the restoration of function in parts which had previously been injured or diseased. Proper construction or reconstruction were the basic principles of orthopedic surgery. Medical treatment alone or surgical treatment alone, which usually stopped with the relief of acute symptoms, many times left the individual with limitation of activities that could have been prevented had measures having to do with the preservation of the function in the inflamed or damaged part followed the treatment which had been given during the acute stage. An operation on a bone or joint might be technically most perfect, but unless the performance was executed with reference to later usefulness or unless measures having to do with the restoration of function were instituted as soon as possible after the healing of the wound, the result that should have been perfect might, from the point of view of function, be very poor. During the early years of the war many men finished their surgical treatment with such unsatisfactory functional results that it became necessary to institute measures for the correction of these conditions on a very large scale. It likewise became evident that the first part of the treatment must be planned with reference to that which more strictly had to do with the establishment of function. Not only was this desirable, but it was obvious that there should be some sort of general responsibility for the care of the individual from the time the injury was received or the disease had started until the fullest possible restoration of function that was possible to bring about was obtained. This, of course, applied directly to our civil hospitals, in which to-day many of the results were much less good than was possible, because the surgeon or the physician was interested only in the acute stages and lost interest in a case as soon as these were past. In the American Army the organization of orthopedic work was elaborated in conjunction with the Director of the Division of General Surgery, so there would be no conflict in the natural overlapping of effort. The closest possible co-operation existed with the American Expeditionary Forces between the orthopedic surgeon, the general surgeon, and the internist. The work of the orthopedic surgeon had to do not only with the treatment of those who were injured or diseased but quite as much in preventing disabling conditions from developing. Much of the work of the Division of Orthopedic Surgery in the early months of the war consisted in so directing the training of the men that elements of weakness or strain would be eliminated and the men would be fully equal to the combat demands. Lack of proper physical training led to many of our young men having weak feet, lame backs, round shoulders, sag of the viscera, etc., which made it absolutely impossible for them to stand continued strain. To meet this problem a special training organization was started, to which these men were sent. Lives were lost, limbs were lost, not because of the original wound, but because in transportation, no matter how carefully carried out, unless the part was properly splinted, the loose fragments of bone, lacerated tissue, tore blood vessels and did other damage with disastrous results. To eliminate this element of harm it became necessary to standardize the splints which were to be used throughout the army, with the idea of reducing the treatment of such injuries to the simplest possible terms that were in keeping with efficiency. A special medical board was appointed by General Bradley, in the summer of 1917, which finally selected eight splints which were to meet all needs as they would arise. Not only was it necessary to decide upon the splints, but it became necessary to instruct the medical officers as well as the stretcher bearers in the use of the splints, so that they should be applied to the greatest possible advantage. With such planning not only were many lives saved, but in the entire A. E. F., with its over 200,000 battle casualties, there were less than 4,000 cases of amputation. To provide proper handling on the battlefield meant the careful training of the stretcher bearers or ambulance corps men so that the splints could be applied in the most efficient manner and with the greatest possible speed. The standard worked out in the British Army, under the direction of Colonel Gray, required that a stretcher bearer should be able to apply a Thomas splint with traction and with a dressing to the wounded thigh in a case of gunshot wound of the thigh in not more than two minutes' time. Training of the stretcher bearers and ambulance men in this work became part of the work of the Division on Orthopedic Surgery. Since it was necessary to move most of the cases from time to time to hospitals further and further in the rear, it was necessary to have some standard method of treatment, both as regards sterilization of wounds and as regards the positions and splints used. This led to a careful standardization of the positions in which fractures of different types were to be put up, as well as the kind of splints to be used, so that it was possible to move a patient from one hospital to another without disturbing the fragments seriously or without changing the general alignment of the bones. This resulted so satisfactorily that the transportation of the wounded, which at first had been viewed with considerable alarm, was shown to be a matter of relative simplicity, with very little harm resulting to the patient. Several thousand cases, many with chronic pyemia, were moved during this period, and not one case was moved where it was felt that harm resulted, while many of the men arrived with distinctly better condition, this being due possibly in part to the mental stimulus of being moved toward home, but undoubtedly in part due to the stimulation resulting from the general movement of the body with the vibration that was incident to the train journey. In each of the hospital centers it was expected that the treatment would not only be planned with reference to the most perfect position of the bones that could be obtained, but also the movement or use of the part would be started at the earliest possible moment. With the standard method of treatment it had become possible to have certain types of injuries which had proven particularly troublesome, such as injuries of the hand, at work, either in the ward or the curative workshop, using their hands in two to three weeks from the time the wound was received. This method not only resulted in more rapid healing of the wound but in a more perfect functional condition. With knee joint injuries similar methods were used, with the idea of using the joint as much as possible without causing irritation or inflammation. The standard method of treatment showed its value when it became necessary to transport large numbers of wounded men who had previously been considered non-transportable, and for whom it was expected treatment would be required for many months in France. For transportation practically only four types of splints were used for the extremities, or were demonstrated to the ship surgeons as the cases were put on board. The work of the Orthopedic Divi-

sion as it was carried on in the American Army developed practically nothing entirely new. The desirability of good posture had perhaps been strikingly emphasized, and greater emphasis had been placed upon the ultimate condition of the injured man than had been possible in our civil hospitals or than had been appreciated by the people under ordinary conditions. Not only had the United States Army insisted that the best medical and surgical care be given, but that such detail as the curative workshop, the early employment of occupation at the bedside, should all have their place and be fully developed. In our civil hospitals not only was it obvious that standardized methods of splinting in connection with the bone and joint injuries would be used, but also that in our civil hospitals the reconstruction aide would have her place the same as in the Army.

Dr. Dean D. Lewis of Chicago said they had been accustomed to regard all the different units in hospitals as separate and distinct. In the early part of the war the surgeon did the surgery and sent the man back to a base hospital, where he was examined and sent further back or to a replacement camp from whence he could be returned to his division. All the reconstructive work was reserved for the hospitals at home. This was found to be a mistake. Reconstruction should begin as near forward as possible. A consulting neurologist should be chief of transportation and neurologists should be in the evacuation hospitals operating and supervising operations. The chief of an evacuation hospital should be surrounded by surgeons of ability who should absolutely control the operation. There were two surgical conditions that should be given special consideration, namely, nerve injuries and osteomyelitis following compound fractures. Peripheral nerve sutures should be done in the evacuation hospital. If they delayed doing these operations for several months results were not so satisfactory. Another point was that the treatment of compound fractures should be more radical. All bone fragments should be removed from the medullary cavity of bone and from the soft parts. If a thorough débridement had been effected in many cases of this class the number of cases of osteomyelitis would be fewer. In cases of osteomyelitis with long tunnels in the bone, the walls of the bone should be removed so that the soft parts could collapse and fill the gap. Cases of osteomyelitis had been received at Fort Sheridan with 23, 24, and even 28 sequestra. The only way in which to cure osteomyelitis was to take an *x*-ray to locate the fragments and then radically remove all infected bone. These patients should not be kept in the hospital until they had reached the maximum of improvement, because they became hospitalized; they should be kept only long enough to obtain such a degree of improvement as would enable them to make a living, and take their place in civil life.

Dr. Nathaniel Allison of St. Louis said that Dr. Cushing had spoken of their experience in war surgery and of the transfer of the lessons they had learned to civil and industrial surgery. The surgery of the forward area of the army had given several very useful lessons for civil surgery. The splints that were applied to fractures were not put on by doctors but by enlisted men of the Medical Corps, and he dared say they were put on just as well in the majority of instances as though they had been put on by doctors. If it was possible to splint fractures immediately and thus prevent shock, it seemed that this was one of the lessons of the war that should be applied to civil conditions. At Bellevue Hospital Dr. Hartwell stated that every ambulance was now equipped with Thomas arm and leg splints and the ambulance drivers were instructed in the application of these splints; as a result of the application of these splints to fractures at the place where the injury occurred there would perhaps be less shock. It was soon recognized in the American Expeditionary Forces that if men were not killed outright by their wounds they died of shock in many instances, and this was particularly true of fractures of the femur. In the Fall of 1917 they lost a man from a simple fracture of the tibia who was carried three-quarters of a mile through the trenches to the first aid station where he died unsplinted. That experience taught the Medical Department of that division a very valuable lesson. Shock was discussed in the Medical Section of the American Medical Association last week. It seemed that the prevention of shock had been given scant consideration; much had been said about transfusion and the cause of shock but nothing about the prevention of shock. It was well recognized in the British Army and in our army that the Thomas splint should be pushed as near the front lines as possible in order to prevent shock from injuries to muscles and nerves caused by the impingement of fractured bone. In the instructions given to the stretcher bearers three things were emphasized: first, they must carry the splints and apply them as soon as possible; second, they should have a dressing packet to stop loss of blood; and, third, they should have a blanket to keep the patient warm. These things were insisted upon together with a tourniquet which was rarely required to stop hemorrhage. This lesson could be transferred to our civil practice with great advantage, because, as was well known, the patient, as a rule, received scant attention until he reached the hospital where his shock was then treated. Another interesting lesson of the war was that shock was lessened by reassurance. A wounded man was usually very much frightened, or very angry; some were much frightened, but usually they were very angry, and it greatly improved the condition of the men if they were reassured and quieted. If a man was given a hot drink, properly splinted, and hemorrhage controlled, shock, as a rule, did not manifest itself. (This referred to fractures of the femur.) If we could apply this to our ambulance service and have the internes instructed in accordance with this knowledge, these lessons of the war might be transferred to civil life.

Colonel H. A. Bruce of Toronto, in response to an invitation to speak, thanked the President for calling upon him and for the opportunity of having heard so many interesting things in connection with the work of reconstruction. He said he felt that they had been very much benefited, but owing to the lateness of the hour he would forbear going into detail.

Colonel George E. Brewer of New York said he felt like Colonel Bruce that they had heard such an excellent exposition of the methods used that it would be a pity to burden the audience with more. He wished, however, to emphasize what Colonel Allison had said about the prevention of shock. There was no question but that the application of these splints as soon as possible after the wounds were received, particularly in wounds of the long bones and those associated with the many lacerations, was more effective than any one factor in the prevention of shock. It was to the everlasting credit of American surgeons that they had learned that before we went into the war.

Colonel William Darrach of New York said the question of reconstruction was one which was going to occupy our minds and attention very thoroughly from this time on, and not only as applied to the surgical treatment of wounds but to the training of the oncoming surgeons and medical men in the United States. He did not think there was anything that had impressed him more than the humiliation caused by the defects in medical education during the last sixteen or seventeen years, and the realization of how far we had fallen short in presenting to the medical student the practice of every day use of the things we knew. One of the greatest things in reconstruction was to start in cleaning house in our own bailiwick in the practice of medicine, and this was one of the greatest problems in reconstruction.

President's Address: Epidemiology and Recent Epidemics.—Dr. Simon Flexner of New York made this address, which he prefaced by saying that to be the active presiding officer of the Congress of American Physicians and Surgeons, the most representative body of the medical profession, if not the largest, in this country, was an honor which if he undertook to tell how much he appreciated it, would not only transgress the rules of the organization as regards brevity, but words would fail him. He said he would therefore proceed with his address, the subject of which had been suggested by the extraordinary stress of the calamities through which the world had passed during the past few years. It seemed fitting that a body, consecrated as this body was to the preservation of life and the amelioration of suffering, should from time to time take

stock of its knowledge. This thought suggested the subject of epidemiology. Great waves of disease had swept over the world in these recent years and had caused appalling devastation. First, there was the extremely severe epidemic of poliomyelitis which passed over the country, attacking every portion and leaving a mark which would not be removed during the life time of some of its victims. In New York and in contiguous states the epidemic was most severe. New York, with approximately 20,000 cases, was the center of this epidemic, and those who studied it agreed that there was no parallel in that locality. Of these 20,000 cases one-fourth died, one-fourth recovered, and the remaining one-half either died later or suffered from the effects of the disease to such an extent that it would have been more merciful had they not survived at all. In 1918 a disease began in the military camps, a streptococcus infection localized in the main part in the lungs and incidentally affecting the pleura. This also caused a large number of deaths, and brought about one of the conditions which made necessary some of these reconstruction and rehabilitation measures about which so much had been said this afternoon. This form of streptococcus infection increased in intensity, spreading to a number of the camps and subsequently to the civil population; it then died away. But this was almost insignificant in comparison with the influenza epidemic that followed, so that really no comparison could be drawn. The influenza was responsible for the greatest number of deaths during the same period of time of which we had record, killing far more than did the war, so that the two calamities were hardly to be compared. Yet in viewing the psychological effect of these calamities on the nation and the people, one was struck by the fact that the war had caused in its results a great attitude of revulsion, while on the other hand, in the presence of such a devastating disease we were quite unmoved. This revealed a peculiar attitude of mind, and showed that the great mass of human beings were not yet emancipated as regards their knowledge of disease. The various bodies of medical men should combine to correct this irrational attitude. Until people regarded ill health and disease as somewhat similar at least to battle casualties, we would get forward very slowly. This was the psychic time for approaching the goal of preventive medicine, namely, the prevention of these great catastrophies. Speaking of the three epidemic diseases which had recently been so devastating, Dr. Flexner considered poliomyelitis first. He said that a microbe was the cause of the disease, but it may have eluded their view under the microscope. They were not sure they had seen it. Again it was possible that they had seen it, but, whether they had or had not seen it, they were capable of stating in a very concrete way that it was present on persons and no one had shown definitely that it was present anywhere else than on persons. They knew how it got into the body and its mode of egress through the nose and throat. They knew the nature of the germ and the mode of its dissemination, yet they were powerless against such epidemics as had occurred in New York State. Had they put into operation such measures as were based on their knowledge, theoretically they would have been able to control such an epidemic, but practically it was a debatable point whether they were able to control the spread of this disease. It was not sufficient merely to identify the organism, but there were qualities of virulence which were subject to alteration and concerning which we had little knowledge. In all instances of this sort direct measures for the control of disease could be put into effect to just such an extent as the public mind was prepared to receive knowledge of the methods which were assumed to control the disease. To popularize medical knowledge should be the great goal of medicine. In the recent epidemic of influenza they were confronted with the question whether to deal with it as with poliomyelitis. They had the same fundamental knowledge. An influenza epidemic was recorded in the 16th Century in regard to which there was much to be read and inferred. If one compared the descriptions of that epidemic with those of the recent one, he would find them almost similar. In connection with the last epidemic, that of 1889-1892, it appeared that the great discovery was the identification of the Pfeiffer bacillus, or, as it had come to be termed, the influenza bacillus. If one asked whether the position of the Pfeiffer bacillus as the cause of influenza was as strong to-day as at that time the concensus of opinion would be that it was not. If one asked whether this organism had been excluded as the cause of influenza, again we should have to say that it had not. The span of time which had elapsed between 1892 and 1918 represented one of the most active periods in some respects through which medical knowledge had passed in all its history. He referred particularly to the organization of laboratories and the laboratory as an accessory to medical practice and the application of knowledge to clinical purposes. With the laboratory equipment, organization, and personnel, there should be a frontal and mass attack against these problems such as would have no parallel in history. Notwithstanding the fact that there had been a large amount of laboratory study given to the subject of influenza, opinion was still divided as to whether a visible organism was the cause of influenza. Perhaps all the laboratory revelations had not been published, and it was quite possible that there was work well under way which would be revealed in the near future. It was quite possible that a filterable virus might be the cause of influenza. Indeed it was possible that there was a whole world of microorganisms too small to be seen with our most powerful microscopes, and that one of these had been evoked in this influenza epidemic. There should be no doubt that influenza was caused by a microorganism, just as typhoid fever or meningitis, or any of the well-recognized microbic excitants. It was fundamental that that view should prevail. Anybody who had studied the history of microbal invasion or anybody who had studied the influenza epidemic must come to the conclusion that the cause was something that attached itself to persons and was carried about by them. These epidemic diseases had endemic homes in contradistinction to their epidemic or temporary homes. There were many records showing that the endemic home of influenza was on the Russian border of Turkestan. It had always begun there and had traveled along trade routes as rapidly as the transportation of the times in which the epidemics occurred. In this last epidemic it had spread both east and west. It always took its name from the place at which it was identified, in this instance Spanish Influenza because it was identified in Spain. It appeared with an extraordinary degree of suddenness and was disseminated almost instantaneously over a wide area. The spread of the epidemic in 1840 was a good example of this pandemicity. The cases were few in number at first and then there were more and more until whole communities fell victims to its onslaught. The curves of the progress of poliomyelitis and influenza were extremely similar, differing only in speed, poliomyelitis taking weeks or months to reach a given point and influenza taking days or weeks. Despite the common opinion, there was no mystery in regard to the spread of these diseases. When the organism had gained access to the body it might or might not cause the disease. As has been said, diseases had homes. If one studied the epidemics that began in 1906 and culminated in 1916, it would be found that they started in Northwestern Europe, Norway and Sweden. This was sufficient concerning transmission. He might therefore turn in conclusion to such questions as were related to the eradication of these diseases. Mass control of these diseases was futile; every effort for control should be made in their endemic homes. The epidemic of influenza came in waves. The first wave was not likely to be so destructive, whereas the second was likely to be destructive, and complicated by pneumonia. This constituted a fatal form of the disease. What were the practical measures for eradicating these great calamitous epidemics? By examples and by learning all the conditions surrounding the nature and mode of conveyance, it was found that practically very simple methods served to eradicate the trouble. The point was to proceed to the endemic focus where the disease existed under relatively simple circumstances and to carry out eradication there. This principle had been applied succesfully to the control of yellow fever. Would it not be one of the great tasks of the medical profession to clean up an endemic region, like the Eastern border of Russia, from whence came

an epidemic that caused death to 10,000,000 people? Would not the effort be better spent in attacking the disease on its own ground instead of meeting it after it had begun its epidemic pilgrimage? It would be well to find and choke poliomyelitis in its lurking spots of Northern Europe before it had assumed epidemic proportions throughout the world. These suggestions could be carried even further in eradicating the bubonic plague which lasted twenty years and cost 10,000,000 lives. As was known, the organism that caused bubonic plague was harbored in the rat in the bubonic form. It was only when the pneumonic form appeared that it was communicated to man. By constant contact the rat became immune and the diminution of cases was not due to sanitary measures, but to the changes in the rat which made it an unsuitable home for the bacillus. The same phenomena had been noted in measles; by exposure the Western races developed a certain capacity for resistance which the Eastern races lacked. In concluding, Dr. Flexner said that eradication was by no means impossible. At periods of great destruction of human life had come changes in human sentiments, leading sometimes to great human improvements. This war had produced a great revolution in human thought. Could not intelligent communities hold their health officers responsible for disease as a nation had proved that it could hold its representatives responsible for great misfortunes or war so that any one who did his part ill would suffer the consequences?

Second Day—Tuesday, June 17.

The Medical Aspects of Reconstruction.—Dr. W. S. Thayer of Baltimore spoke on this subject. He stated that in the ordinary practice of medicine, apart from the fundamental question of diagnosis, the doctor found himself concerned with the closely interwoven problems of the prophylaxis and treatment of disease. The war had emphasized the importance of that other duty of the physician which was so difficult often to fulfill, namely, the care of the convalescent, that part of medicine which might properly be regarded as reconstruction. When the grave symptoms of disease had passed, the activities of the physician too often came to an end. In general with the discharge of the doctor in private practice or of the patient in hospitals, the duties and responsibilities of the physician as regards that particular individual were considered to be at an end. In war conditions were different. The patient was not his own master; he was the servant of his country and his master needed his services as quickly as they might be available. In other words, in war time in France, the value of convalescent care and medical reconstruction in its narrow sense came to its proper place in the practice of medicine. The individuals with whose rapid and efficient rehabilitation with which medical reconstruction was concerned were briefly classified as follows: (1) Instances of exhaustion, concussion, fear, anxiety neuroses and psychoses of all kinds, which if not arrested at an early date passed down the line of communications and under the influence and surroundings of a general hospital became fixed. (2) The mildly gassed, who were especially liable to present annoying psycho-neurotic phenomena if not properly cared for. (3) Psychoneuroses of a more serious character, which needed treatment and care at a base hospital. (4) Convalescents from all types of non-disabling wounds, gas intoxication, operations and disease. (5) Patients suffering from that general complex of symptoms known in the A. E. F. as effort syndrome. Tuberculosis might also be added though those showing signs of tuberculosis were not to be returned to the front. The convalescent camps for the first time tried to determine the average time for complete convalescence in a variety of diseases. An article on this subject was to be published by Dr. Bridgeman. The average time for recovery from certain diseases was as follows: Influenza, 31 days; pneumonia, 58 days; acute bronchitis, 36 days; mumps, 39 days; measles, 27 days; scarlet fever, 77 days; catarrhal jaundice, 38 days; diphtheria, 57 days; tonsilitis and sinusitis, 34 days. It was found that a large number of men suffering from exhaustion, fear, concussion, anxiety and a variety of lesser functional nervous phenomena, if allowed to lie about in hospitals, rapidly lost morale, discipline, and physical vigor. In others of more impressionable character ill judged treatment in a general hospital resulted in fixing a variety of psychoneuroses, which once established were difficult to overcome. It soon became evident that measures must be taken to hold these men as near the front as possible where they could be given rest and suitable treatment and study. These were the main problems of reconstruction at the front, while at the base hospitals the problems were equally as urgent. Excellent results followed the stationing at the front line hospitals of trained psychiatrists under the direction of Colonel Salmon. Here many instances of simple exhaustion or fear or concussion, which previously had been sent to the rear, perhaps as gassed, were held, and suitably treated, and returned to their organizations after two or three days rest. Under favorable circumstances it was found that as many as 80 per cent. were returned to their divisions. The average during the Argonne offensive was 65 per cent. In times of special stress the application of such measures was not possible at crowded field hospitals in the corps and divisional areas. The wise measure was accordingly adopted of establishing in the army area special so-called neurological hospitals and special gas hospitals. The former under Colonel Salmon and the latter under Lt. Col. Richard Dexter. From the neurological hospitals 60 per cent. were returned to the front. From the gas hospitals, many simply exhausted were also sent to such corps as had rest camps or replacement depots, and thereby saved to their divisions. Dr. Thayer described more in detail the work at the Neurological Base Hospital 117, at Lafauche, and of the Orthopedic Retraining Centers, the first of which was established at Vosges by Dr. Goldthwait. The value and importance of the work of retraining, the complexity and delicacy of the problems involved, the necessity that the director of such a camp should be possessed of tact, judgment, and savoir faire, brought it about that in the British service the position of commanding officer of a convalescent camp came to be one for which officers of the very best qualifications were sought. Both the mental and the physical aspects of each case were considered, and to each of their institutions an officer was assigned who had special training in cardiovascular diseases. This work was supervised by Dr. Col. Alfred E. Cohn. Dr. Thayer spoke briefly of the measures designed to care for tuberculosis soldiers, and then went on to a consideration of the advantages that would accrue from the application of such a system for the care of convalescents to industrial institutions. He said it was easy to comprehend the grave difficulties which would attend the conducting of such an institution in civil life. Nevertheless it was clear that convalescent departments were needed and should be started in connection with our large hospitals, not convalescent homes, but institutions under the charge of active and specially trained physicians, in which every arrangement for the well considered rehabilitation, mental and physical, of the convalescent might be carried out. Here in America the admirable work of General Hospital No. 9 at Lakewood, N. J., had shown what systematic physical and mental training might do for the large body of slightly subnormal individuals from whose ranks a very considerable percentage of effort syndrome was derived. The treatment of these cases differed in no essential way from that which should be afforded to the convalescent in civil life. If our experiences in this war should help to awaken a new interest in the care of convalescence and should convince the medical profession and the general public of the importance of suitable physical training in the rehabilitation of the inefficient, a beneficial advance would have been made in the art of medicine.

Cardiac Phase of War Neuroses.—Dr. Alfred E. Cohn of New York presented this subject. He gave a historical review which showed that the condition known as "irritable heart of soldiers" was recognized in previous wars and had been described by DaCosta in 1871. He described the condition, which might present the following symptoms, though they were not necessarily found in one individual: palpitation, cardiac pain, rapidity of the heart rate, shortness of breath,

headache, giddiness, insomnia, hyperesthesia of the skin, blueness of the lips and hands, mottling of the skin, indigestion, abdominal distension, diarrhea, itching, and sweating. Usually the heart was of normal size, though occasionally it was enlarged. In Great Britain a special service had been set aside for the study of this condition, under the direction of Sir Thomas Lewis. In this country a similar reservation was made at General Hospital No. 9, at Lakewood, under the supervision of Major Francis Peabody. The symptomatology studied under this regime had not been found to differ materially from that described by DaCosta. All observers here agreed as to the large numbers of these cases, and that in the majority there was no organic disease of the heart. The differentiation of the irritable heart from the hyperthyroid heart presented difficulties, the two classes having many points of similarity. In both the rate was rapid, sometimes there was enlargement; abnormal sounds associated with the rapid rate were common; tremor was common and there was exophthalmos or a semblance of it. The latter symptom was often due simply to anxious expression which apparently gave prominence to the eyes. The tremor of irritable heart was coarser than that of Graves' disease and the heart rate fell during rest and sleep instead of being continuously maintained. The metabolism rate in irritable heart was not above the normal, whereas it was uniformly exaggerated in Graves' disease. Before the war, owing largely to the influence of DaCosta, these cases were considered related to cardiovascular disease. The writer considered, however, that there was no organic functional disease, and it remained to establish a connection between these symptoms and the neuroses. Patients usually presented those states classed as anxiety neuroses and psychiatrists had interpreted them as cardiac manifestations of neurotic character. Most cases of effort syndrome occurred among men who had been gassed, and although the *x*-ray failed to show persistent cardiac or pulmonary abnormality, the men still complained of pain in the chest and shortness of breath on exertion, the nature of which was obscure. The possible explanation might lie in the fact that following a primary rather lax discipline, an over-exaggeration ensued of gas dangers, and a veritable "gasphobia" developed among the men. Individuals also showed a varying susceptibility to the effects of gas and suffered in unequal degrees. Thus it might develop that this was an explanation of the relation of effort syndrome to gas poisoning and also to the nervous symptomatology. Exact investigation was needed to throw more light on the matter. The relation of the "anxiety states" to war was abundantly clear. The timorous and the hardy naturally varied in their reactions. Inferiority did not seem to depend on heredity. The men who failed first were not necessarily the inferiors. The sights and sounds of actual warfare wore down the resistance of the most enduring. It would, therefore, be difficult to predict who would succumb. Two factors stood out, native predisposition and time. The constitutionally predisposed fell out here first; those with slightly better endurance fell out in France; on the whole those that reached France were superior. Another point indicating the neurotic origin was that these symptoms were unknown in the severely wounded—those whose faces were turned away from the front. This was true of severely gassed and of prisoners of war. The prognosis of these conditions depended upon their origin. If they were thyroid in nature, or dependent on cardiac abnormality, they would be identified with these conditions. If they were neurotic, suitable treatment would reestablish them. The treatment also depended upon the diagnosis. DaCosta put them to bed and treated them with drugs. This was not found beneficial in the present war. The system of Lewis, that of graduated exercise, for the purpose of both classification and of treatment, was of signal benefit. The experience of the British in the treatment of these cases was made use of by the A. E. F. It was found that the convalescent camps should be separated from hospitals by several miles. The convalescent camp was designed to give back morale and courage to the soldier. The camp atmosphere had to be attractive. The soldiers were kept on modified but strict discipline. They were instructed and taught to amuse themselves. Such work naturally called for the greatest tact and organization. The British attained their success in this work by dint of hard experience, and no doubt the A. E. F. would have attained similar efficiency had not the armistice cut short their career. This experience had an important application to civil life, where large numbers of these subnormal persons were to be met. There remained many problems in the pathogenesis and mechanism of the disorder to be studied. They felt the syndrome was essentially allied with the anxiety and fear neuroses and that it was cured by measures designed to influence the neurotic state.

Reconstruction in Nervous and Mental Disease.—Dr. PEARCE BAILEY of New York, formerly Colonel in the Medical Corps of the United States Army, Chief of the Section of Neurology and Psychiatry, delivered this address in which he said that the ideal of reconstruction in nervous and mental diseases which seemed to him to shine out above all others at this time was that which, vivified by the lessons of the war, had for its object the improvement of the nervous stability of the whole nation. It should not be confined to those who lately wore or were still wearing the uniform, but should include all others, the less fortunate and their children. It should be a civil rather than a military reconstruction. There were practical reasons for this. As far as the treatment and rehabilitation of the soldiers themselves was concerned, the methods employed in the Army, with a single exception, were the same as should be a part of a general civil program, and actually were matters of therapeutic routine in the most progressive communities. It was by no means meant to belittle the importance of the service rendered nervously ill men by neuropsychiatic officers in this country or in France, but, in this country at least, the constructive service of these officers was less therapeutic than preventive, as it consisted in the exclusion from the troops of candidates for service who, if accepted, would weaken the organization upon which the country's existence depended. It was a matter of no little concern that 72,000 young men, inapt from nervous causes, were discovered and abandoned, but the real concern was that they were here, the war did not make them, and they were in no sense products of the mobilization. Their enforced abandonment had disclosed how little provision we had made for the study of the conditions which were responsible for them, or for the treatment and control of either individuals or conditions. The neuropsychiatric examinations had given a conclusive and final demonstration that mental and nervous disease ranked among the chief of our public health problems. They had unearthed a vast field in preventive medicine which, up until now, was almost untouched. The total of 67,417 which was the number of fully classified neuropsychiatric rejections from the Army up to Feb. 1, 1919, put nervous and mental diseases fourth on the list of rejections by clinical groups, its group being succeeded by those of: (*a*) eye, ear, nose and throat; (*b*) bones and joints; (*c*) heart and blood vessels. The nervous and mental group had a sanitary and economic importance not indicated by its relative standing. The other defects mentioned by no means implied an inferiority which would prevent the individual from competing on equal terms in many civil occupations. Rejection for nervous and mental defect implied not only an almost universal vocational inequality, but also, and this especially in the most numerous class, the feebleminded, that the individuals checked civilization and were certain rapidly to increase their own kind. All the patients passing through the control of the neuropsychiatric officers were unwounded and might be included in seven groups as follows: psychoses, 11 per cent.; neuroses, 15 per cent.; epilepsy, 9 per cent.; organic nervous diseases or injuries, 18 per cent.; inebriety (alcohol and drugs), 6 per cent.; mental defect, 32 per cent.; constitutional psychopathic state, 9 per cent. It must be emphasized that the potentially insane became insane in the army more frequently than they did, at least to require custodial care, if left in civil life. No new types of mental disease were differentiated, but additional proof was forthcoming that

the outlook in military psychoses was brighter than in those which developed in civil life. The experience demonstrated the importance and value of the modern methods of care which were established throughout the military hospitals. It was shown that physical restraint was rarely necessary and imperilled recovery. In respect to the insane as a nation-wide problem, the war had shown the economic as well as the humanitarian importance of proper care. Few of our State Hospitals now had the personnel required to furnish such care, a want that we should hasten to supply. The system of state hospital mental clinics should be widely extended. Dr. Bailey said it was unnecessary to speak of the treatment of acute cases at the front, as all were doubtless familiar with the achievements of Colonel Salmon in this direction. The treatment of the chronic or inveterate military cases, a distinct reconstructive problem, required a careful classification of the patients' personality, a hospital treatment where, after all physical needs were attended to, the atmosphere was such as to change the patients' point of view. This was done by explanation, encouragement, and by any of the adjuvants of suggestion. In the hospital the patient should be brought as quickly as possible to do things for himself. The mobilization demonstrated a degree of feeble-mindedness in this country which, while not far out of accord with the previous estimates of experts, took most thinking men by surprise. Moreover there were more mental defectives rejected at draft boards and camps, or discharged soon after enlistment than any other neurological or psychopathic patients. They constituted 29 per cent. of all neuropsychiatric rejections among whites, 49 per cent. among blacks. The total number exceeded 24,000, of which Maryland had the highest proportion and Arizona the lowest. In certain sections large numbers of them were foreign born. There was little doubt from attempts to train mental defectives during the war that the future interests of the country would best be subserved if they were not accepted for military service. Both State and Federal Governments should take up the problem of feeblemindedness immediately. It was for them to realize that the feeble-minded, useless, costly and dangerous if left to themselves, as for the most part they now were, could be useful as agents in food and other supply under proper management segregated on farms. The lesson in reconstruction to be drawn from the war in this respect was that a livelier interest in this great problem which was almost untouched, should be aroused, and that all possible help and encouragement should be extended to governmental and social agencies which were trying to care for this class of individuals. The basis of the whole sociological program was the recognition and classification of subnormal personalities, and a supervision in accordance with the varying needs of the different classes. If there is any one point at which intensive psychiatric and psychological study should begin it was not difficult to be certain where that point was. It was in childhood and early adolescence. The principle of psychiatric and psychological classification of subnormal children should be widely extended. It should be followed by assignment to special classes for such as could be benefited by such classes (90 per cent.) and institutional care for others. At the end of the school period the subnormal child should not be turned loose on the community but placed under a parole system directed by a suitable commission, and in the event of their failure, committed to an organized institution, where they could receive the training denied them at home. The educational departments of our states and municipalities were therefore the most promising agencies in the control of the menace of nervous and mental disease and criminality. But they could not do this unless we of the medical profession interested ourselves in their problems and assisted them by supplying competent advisors and workers. If all the various measures outlined were adopted, one would be safe in predicting an immediate drop in our insane rate, criminal rate, and an increase in our productiveness. One reason they had not been adopted would be found in the indifference on the part of the medical profession to nervous and mental disease. Medical schools and general hospitals gave most meagre and grudging representations to neurology and psychiatry. Indeed we were so far behind in these matters that there was a question if American neurology and psychiatry would ever attain the position they should have unless there was established a special foundation for research and teaching.

Dr. Francis W. Peabody of Boston said that Dr. Cohn had given them a very clear account of the irritable heart of the soldier, a condition which a year and a half ago appeared to be clinically a very severe condition to all of them. At General Hospital No. 9, at Lakewood, they had attempted to discover some organic basis for this symptom's complex. They had made many observations of all kinds that might possibly throw some light on the matter; they had made investigations in the blood chemistry, basal metabolism, and in fact had employed all modern laboratory methods for ascertaining deviations from normal conditions, but could get no results. When they came to study the personality of the individual it became quite clear that the most important factor was neuroses. They had found that the highly neurotic were particularly sensitive to adrenalin, owing to its effect on the sympathetic nervous system. This opened up the psychological problem of the relation of the hypersensitive nervous system and the neurotic constitution. Further study showed that these cases might be classified into two different groups, namely, those with a normal background and those who were constitutionally inferior. The latter constituted the most important group, and were not the product of the war. A great many of them had an inherited neurotic taint and most of them had had more sickness than was normal. They were regarded as weak and not strong, and most of them had been regarded as having weak hearts. It was extremely unfortunate that the idea that many of these individuals had that they possessed weak hearts was the result of their having been examined by a physician and told that they had organic heart disease when none existed, and that had started them on the career of semi-invalidism. Believing they had heart disease they had avoided all exertion which caused them discomfort. These individuals broke down partly because of the physical strain, but more particularly because they could not adapt themselves to the life of the army. They found themselves leading a life that had very little respect to the individual and it was found in this particular group of men that there was a decrease in the strength of the skeletal muscles of 50 per cent. In the rehabilitation of this class of men one of the first essentials was an understanding of the personality of the individual and of the difficulties with which he was confronted. It was found that graduated physical exercises were a most important therapeutic adjunct. They were found to almost double the physical strength of a patient and they had a very favorable psychophysical effect. How many could be made useful soldiers was an open question but certain it was that many of this group had grown up to usefulness in civil life. It was important to find that there was this large group of underdeveloped individuals who were not handled properly by medical men and which if properly handled when the next war came would lead to the result that there would be fewer cases of irritable heart of soldiers.

Physical and Mental Rehabilitation of Disabled Soldiers of the United States Army.—Col. Frank Billings, M. C., U. S. Army, exhibited a motion picture film showing the reconstruction work being done in the military hospitals throughout the country. He stated that the film had been made by a man in one of the vocational schools. While showing the film he gave briefly the policy and principles that governed the reconstruction work in the Army. The plans for the reconstruction of disabled soldiers, later extended to disabled sailors and marines, was formulated by the office of the Surgeon General in August, 1917, and approved by the War Department in July, 1918. He stated that he did not like the term physical reconstruction, but preferred the term rehabilitation and he employed that term in reference to both physical and mental reconstruction. Whatever term was used, the work was defined as continuous treatment to as complete a degree of physical and functional restora-

tion as the nature of the disability permitted. To this end all the measures usually included under physiotherapy were employed, together with mental and manual training, and out-door sports and in-door games. The film showed the entire program of treatment from the time the soldier was received at the hospital of debarkation to his final discharge from the Army. The educational program offered comprehensive courses in technical, agricultural, and commercial subjects. Civilian women worked as reconstruction aides, and a number of organizations, the Red Cross, the Y. M. C. A., the K. of C., Jewish Welfare Board, the Salvation Army, and the American Library Board, had co-operated with the War Department. After describing the special work being done for the blind, the deaf, and those suffering from speech defects, Colonel Billings stated that no deaf man was discharged until he could converse by the lip method, no man with a speech defect was discharged until his defect was corrected as far as possible, and that when the blind were discharged their instruction was continued by the Red Cross. Modifications of curative work were applied in seven military sanatoria for tuberculous soldiers. Previous to the signing of the Armistice 10,000 disabled men were returned to the United States from the A. E. F., and many of these were disabled by sickness rather than injury. Before the signing of the Armistice the curative work was given with a view to returning the soldier to miltary service as it was believed that the vocational training would make a better soldier of him. From the time the Armistice was signed until June 1, 1919, 143,000 disabled soldiers were returned to the United States for continued treatment in hospitals. Many who did not need continued treatment, but who were under par were simply kept long enough to harden them before discharge. Physiotherapy of fairly good character had been instituted in 44 general and base hospitals which were equipped with appliances for giving hydro-, electro-, thermo-, and mechano-therapy. They had now a trained personnel of over 800 directors and aides for giving this treatment. They had found that about eight per cent. of the disabled men were illiterate, and as they had examined some 10,000 in arriving at this average they felt that it was a fair average for the entire Army. To meet the needs of these men schools had been established which were also schools of Americanization. The shop and school included three divisions: (1) academic and professional courses; (2) technical courses; (3) recreational courses. For the month of April, the total enrollments were: in the academic courses, 7,620; in the technical courses, 15,705; recreational enrollments, 30,356. The total enrollment, including ward work, was 52,739 for that month. Work was prescribed only as a curative measure in the hospitals and the dose was regulated as carefully as that of any drug. In prescribing the kind of work the patient was to do the surgeon kept always in view the restoration of function. The types of cases enrolled in the educational service included the following: orthopedic, tuberculous, wounded, nerve injuries, amputations, functional neuroses, injuries of ear, eye, nose and throat, gassed, cardiovascular, genito-urinary, nephritis, facial and cranial injuries, arthritic, blinded, dermatological, gastrointestinal, deafened, defective speech, general medical and surgical conditions. The convalescents formed a large percentage. Since the Armistice had been signed convalescent camps had been established in various parts of the country and soldiers had been sent to the centers nearest their homes. Here they received the final hardening and curative processes by means of setting up exercises and military drill. The number of men so trained since the Armistice numbered 47,853 to the present date. In spite of almost insurmountable difficulties it was believed that physical reconstruction of the soldier had been of the greatest value in maintaining discipline, promoting morale, diversion of the soldier's mind from his disability, and arousing his interest in education which would overcome his handicap, as well as in his physical and functional restoration. In the application of physio-therapeutic treatment very high standards of efficiency had been reached in application, equipment and personnel. Many of the women employed in this work were college women, and their efficiency had been very high. Many of them had worked for less compensation than they would obtain in civil life. Each hospital had published a newspaper devoted to the interests of the disabled. This had given the opportunity for training in editorial, story, and advertisement writing, and had maintained the morale and interest of the hospital personnel and patients. Finally, it might be said that the establishment of measures of physical reconstruction in the treatment of disabled soldiers had been so beneficial that it would create, it was believed, a demand for the application of like measures in the treatment of patients in civilian hospitals in this country.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Ohio State Board of Medical Examiners.

December, 1918.

(*Concluded from page* 46.)

OBSTETRICS.

1. How would you manage a case where there was a marked protrusion of intestines into the pouch of Douglas complicating a delivery?
2. What general consideration should guide you in the selection of a wet nurse?
3. What general objections should be urged to an attempt at version after delivery by forceps failure?
4. Outline a rational treatment for persistent vomiting of pregnancy. What is the last resort?
5. State some principal reasons for uterine subinvolution. Where should the uterine fundus be at the end of the tenth day of the puerperium?

SURGERY.

1. Outline briefly technique and surgical procedure in inguinal hernia.
2. In what class of cases do you recommend removal of the thyroid glands?
3. Give three important rules in skin grafting.
4. What is Dakin's solution, and in what class of cases is its use indicated?
5. Outline treatment of compound comminuted fracture of the humerus, upper third.

DERMATOLOGY, SYPHILOLOGY AND DISEASES OF THE EYE, EAR, NOSE, AND THROAT.

1. What is ichthyosis? Give diagnosis and prognosis.
2. Name the principal tertiary manifestations of syphilis.
3. What is cataract? Name the different forms. What treatment is necessary?
4. How would you treat acute suppurative otitis media?
5. Give technique of tonsillectomy.

ANSWERS.

OBSTETRICS

1. In case of *prolapse of the intestine into the pouch of Douglas*, if the condition is recognized early in labor, the protrusion should be pushed up out of the way until the head of the fetus has passed; putting the patient in the knee-chest position and manipulation may help. If this is impossible, labor must be induced rapidly as soon as the cervix is sufficiently dilated.

2. *Selection of a wet-nurse.*—"In selecting a wet-nurse we must consider her age, her general health and development, her probable nervous status, and the age and health of her infant. The preferable age for the nurse is between twenty and thirty years, and multiparæ are apt to do better than primiparæ on account of having had charge of the suckling and general care of infants. A careful physical examination of the applicant should be made by the physician. Constitutional taints, especially syphilis and tuberculosis, must be excluded by a painstaking history and thorough examination of the mouth, lymph-glands, skin, and other parts

likely to show evidences of infection. If any vaginal discharge is present, it must be examined for gonococci. The best breasts for satisfactory suckling are not the large, firm ones, but rather the more flabby and pendulous kind. The nipple must be of good form and size and sufficiently protuberant for easy grasping by the infant, and free from fissures and abrasions. A woman of quiet, phlegmatic temperament, in good health, is to be preferred, as nervous instability has a quick effect on the composition of the milk. A woman whose infant is under six months can usually suckle a new-born baby, but a less disparity between the ages of the infants is desirable if it can be attained. A careful examination of the nurse's infant must be made to exclude any constitutional disease especially syphilis. Such examination will also show how well the infant has thriven upon its mother's milk. The diet of the wet-nurse, when selected, should be as nearly as possible that to which she has been accustomed, avoiding a too great variety and quantity of food. If she is furnished a diet richer and more abundant than she is accustomed to, she will in all probability overeat and bring on either defective digestion or excretion, which will promptly disorder the digestion of the infant. Regular outdoor exercise must also be insisted upon. Several nurses will sometimes have to be tried before a breast that agrees with the baby is found."—(Chapin and Pisek's *Diseases of Children.*)

3. Forceps would have been tried only if the fetal head was engaged; whereas, this condition is a contra-indication to the version. The bag of waters would have been broken before the forceps could be applied; this would make version very difficult or impossible.

4. *Pernicious vomiting of pregnancy.*—"The treatment consists in rest in bed in a quiet, darkened room and the administration of easily digested foods, such as milk, broths, eggs, etc. A careful search must be made for some local exciting cause, and if any such condition is found, it should receive appropriate treatment. Sexual intercourse should be interdicted. The bowels should be kept freely open. Sodium bromide, camphor, cocaine, silver nitrate, cerium, oxalate, hyoscine hydrobromide, antipyrin, etc., are among the drugs used internally. Rectal alimentation may be necessary, and, as a last resort, dilatation of the cervix and internal os, or induction of premature labor or abortion may be performed.

5. *Subinvolution* is delay in, or failure of the uterus to return to its normal condition after labor. *Its chief etiological factors* are: Lacerations of the cervix; absorption of septic products; mismanagement of the convalescent stage of the puerperium, chiefly too early rising; tedious labors; misplacement of the uterus; retained clots or membranes; tumors of the uterus. At the end of the tenth day of the puerperium, the fundus of the uterus should be at about the level of the brim of the pelvis.

SURGERY.

1. *Bassini's operation.*—"An incision 2½ inches long is made over the inguinal canal, exposing the structures of the cord and the external oblique. The external oblique fibers are split from the apex of the external ring to expose the canal. The sac is found, opened, emptied of its contents, and isolated from the structures of the cord up to the internal ring. If the hernia is irreducible, the intestine is freed and returned to the abdomen, the omentum being ligatured and removed. The neck of the sac is then transfixed and tied with silk, and the fundus removed. The stump returns to the abdomen, three or four stitches are then passed through the conjoined tendon and arched fibers of the internal oblique and transversalis muscles above, and the deep part of Poupart's ligament below. These are tied behind the cord. The external oblique is then sutured in front of the cord, leaving just sufficient opening for it to pass through without pressure. The skin is then closed by a continuous stitch. The patient should be kept in bed for three weeks, and should not exert himself for at least six weeks. If the wound has suppurated, or if the case is one in which the abdominal muscles are weak, it is advisable that a light truss should be worn afterward for six months."—(From *Aids to Surgery.*)

2. *Partial thyroidectomy is indicated* in some forms of goiter, "when there are symptoms referable to pressure on the air-passages, esophagus, or blood-vessels, especially if there are signs of commencing cardiac disturbance; and in goiters which are steadily increasing in size. The evidence of a goiter becoming malignant is also a reason for removing it by operation. Kocher considers it advisable to operate if the patient becomes breathless by making pressure on the goiter from side to side."—(Thomson and Miles' *Manual of Surgery.*)

3. *Conditions necessary for successful skin-grafting* are: Proper selection of cases and methods, rigid asepsis, absence of tension, absence of cicatricial tissue, and thorough freshening of the part to be covered.

4. *Dakin's solution* is a solution containing between 0.45 and 0.50 per cent. of sodium hypochlorite. It is used in severe infected wounds, and the solution must be in constant contact with the infected tissues in order to bring about the destruction of the micro-organisms.

5. *Treatment of compound comminuted fracture of the upper third of the humerus.*—"In the treatment of compound fractures the main object is to render the wound aseptic and to give efficient exit to the discharges. For this purpose the patient should in all cases be anesthetized, the limb shaved and thoroughly purified, and the wound enlarged and thoroughly washed out with some reliable antiseptic. It may be advisable to excise torn and dirty fragments of skin, muscle, and tendon, especially when dirt has been ground into them. Loose fragments of bone are removed and portions denuded of their periosteum may be taken away lest necrosis should ensue; where fragments retain any considerable connection with the soft parts they may be left without fear. When a sharp end of one of the fragments is protruding through a small opening in the skin it is first purified thoroughly before attempting its reduction and then replaced, after enlarging the wound in the skin, or a portion being sawn off. Hemorrhage is dealt with in the usual way, and the fragments are placed as nearly as possible in their normal position. If the fragments can be brought accurately into position it is well to fix them by some mechanical appliance; but where the ends of the bone are much comminuted the small portions must be arranged in position as well as possible, and no attempt made to wire them. A good-sized drainage tube is inserted, and if need be, counter-openings are made; the external wound is closed or not, according to circumstances, and dressed and suitable splints are then applied. Under such a régime the majority of cases do well. Immovable apparatus may be used after a time, windows being left in the plaster casing to allow wounds to be dressed."—(Rose and Carless's *Manual of Surgery.*)

In very severe cases the question of amputation will arise. If the bone has been shattered beyond repair, the soft parts so severely damaged that asepsis is impossible and recovery improbable, and the nerves and vessels largely destroyed, then amputation will be necessary.

DERMATOLOGY, SYPHILOLOGY AND DISEASES OF THE EYE, EAR, NOSE, AND THROAT.

1. *Ichthyosis* is a congenital chronic hypertrophic disease, characterized by dryness and scaliness of the skin and a variable amount of papillary hypertrophy. *Diagnosis.*—The characteristic features of ichthyosis are the harsh, dry skin; furfuraceous scales and polygonal plates; the localization of the eruption; the history and the absence of inflammatory symptoms. *Prognosis.*—The prognosis is unfavorable as to cure. Considerable relief, however, may be afforded by proper treatment and the skin can be kept in smooth and supple condition. (Schamberg's *Diseases of the Skin.*)

2. The *principal tertiary manifestations of syphilis* are the late syphilides, with tendency to ulceration and scar formation; gummata of skin, subcutaneous tissue, viscera or muscles; and amyloid degeneration.

3. CATARACT is any opacity of the lens or its capsule. *Varieties.*—"Cataracts may be divided into: 1. *Primary* when independent of any other ocular disorder, and (2) *Secondary* or *complicated*, when accompanying or following some other disease of the eye, such as glaucoma, uveitis, etc.

Cataracts are divided according to the *part of the lens involved* into: (1) *Lenticular*, situated in the

substance of the lens. (2) *Capsular*, affecting the capsule. (3) *Capsulo-lenticular*, involving both lens and capsule. They are also known as: (1) *Partial*, limited to some part of the lens. (2) *Complete*, involving the whole lens. (3) *Stationary*, when they remain incomplete. (4) *Progressive*, spreading, tending to affect whole lens. *Stationary cataracts* may be divided into: (1) *Anterior polar.* (2) *Posterior polar.* (3) *Lamellar.* (4) *Various uncommon forms. Progressive cataracts* may be divided into: (1) *Senile* (cortical, nuclear). (2) *Congenital* and *juvenile.* (3) *Traumatic.* In patients *under thirty-five* all cataracts are of *soft* consistence throughout and *white* in color; such cataracts have no hard nucleus and are known as *soft cataracts. After this period*, the nucleus becomes *hard* and of a *yellowish* tint, and the lenticular opacity is known as *hard cataract.*

Treatment.—Senile cataracts require extraction of the lens, with or without iridectomy; in congenital and juvenile complete cataracts, discission or needling is indicated; for traumatic cataract, extraction may be required; for stationary cataracts, iridectomy, discission or extraction may be indicated.—(From May's *Diseases of the Eye.*)

4. *Treatment of acute suppurative otitis media.*—"Dry heat allays the pain. Warmed water or warmed carbolic acid solution (1:40) may be used. Inflations, aspirations, etc., should be avoided. If the nares are filled with tough secretions, a spray of Dobell's solution may be used. If the pain continues over six hours in a child or over twelve hours in an adult without spontaneous perforation of the tympanic membrane, paracentesis of that structure should be performed. The concha and meatus should be smeared with petrolatum to avoid chapping, and the secretions should be gently mopped off as they appear. Under this treatment the ear usually returns to normal in two or three weeks."—(*Pocket Cyclopedia of Medicine and Surgery.*)

5. *Technique of tonsillectomy.*—"A mouth gag is inserted, the tongue is held down and forward with a depressor; mucus and saliva are removed from the pharynx with a gauze sponge; the tonsil is grasped with stout volsellum forceps provided with a catch to render them self-retaining. The upper blade of the instrument should be in the supratonsillar fossa and the lower inserted into the lower border of the tonsil in such a manner that a part of the capsule and so considerable a portion of the tonsil is included within the grasp of the forceps that they will not readily tear out. The tonsil is now pulled strongly toward the median line of the pharynx, so that its extent beneath the anterior pillars is readily seen. While traction toward the median line is maintained, the anterior and posterior pillars are dissected loose from the tonsil by means of the tonsil knife, the tonsil being rotated downward and inward out of its bed or pushed or pulled away from the pillars to facilitate the procedure. Especial attention is directed to the attachment of the tonsil to the anterior pillar at the point where the plica triangularis leaves the anterior pillar to extend backward over the lower third of the tonsils. The capsule of the tonsil extends forward and medianly to attach itself to the edge of the anterior pillar at this point, and hence, severing this attachment, opens up the space behind the capsule and permits the tonsil to sag outward from its fossa toward the median line of the pharynx. The tonsil is attached now only by its lateral portion to its bed, from which it can be still further enucleated by the use of the finger-tip inserted into the supratonsillar fossa, better with Hurd's enucleator, a stout steel curette, slightly curved at the tip, which is about the size but much thicker than the forefinger-nail. The loop of a snare is now slipped over the forceps and made to surround the base of the tonsil, which by the use of the enucleator and finger-tip has become pedunculated and adherent only at its inferior portion."—(Gleason's *Diseases of Nose, Throat, and Ear.*)

THE TUBERCULOSIS PROBLEM AFTER THE WORLD WAR.*

By S. ADOLPHUS KNOPF, M.D. (New York and Paris),

NEW YORK.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY, AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VICE-PRESIDENT OF THE AMERICAN ACADEMY OF MEDICINE; SENIOR VISITING PHYSICIAN TO THE RIVERSIDE HOSPITAL-SANATORIUM OF THE HEALTH DEPARTMENT OF THE CITY OF NEW YORK; FORMERLY CAPTAIN IN THE MEDICAL CORPS, UNITED STATES ARMY.

The importance of the subject which I have chosen for my address this evening makes me feel that never before in my career as an humble soldier in the warfare against tuberculosis have I assumed a more difficult or a more sacred task. My theme involves a world disease and the endeavor to aid in conquering it. I trust that you will bear with the inevitable shortcomings because of the vastness of the subject before us. In order fully to realize the scope of the problem, let us for a moment review the pre-war condition in some of the larger countries of Europe and America.

A little more than twenty years ago, when the world was not at war, there existed among physicians, sociologists, and philanthropists the world over a feeling that tuberculosis was an international medical problem, and that an immense social problem was associated with it alike for all peoples.

It was to our Allies, the French nation, that we are indebted for the first congress for the study of tuberculosis in man and animal, to which foreign delegates were invited. Four such French congresses were held in Paris (1888, 1891, 1893 and 1898). Then followed a congress in Berlin in 1899, called "Congress to Combat Tuberculosis as a Disease of the Masses." The first general international tuberculosis congress was held in London in 1901, a second one was in Paris in 1905, a third one in Washington in 1908, and a fourth one in Rome in 1911. A projected one for 1916 was to have been held in London. It was never realized because the world war had descended like a thundercloud over the entire civilized world and only now seems to be lifting gradually, but let us hope permanently.

As a result of those national and international gatherings prior to 1914, a better scientific understanding of the causes, prevention, and cure of tuberculosis was promulgated throughout the civilized world. A feeling of more justice and greater charity toward the consumptive poor, the realization of the necessity of improving housing and living conditions of the working classes and better general hygienic conditions resulted in a perceptible decrease of tuberculosis in nearly all civilized countries. Villemin, the Frenchman, had proven the contagiousness of tuberculosis; Buddington, the Englishman, was the pioneer of the open-air treatment in specially constructed institutions; two Germans, Brehmer and Dettweiler, and one American, Trudeau, gave to the world rational ideas on sanatorium construction and sanatorium treatment; Robert Koch, a German, discovered the microbic cause of tuberculosis; and a great American, Theobald Smith, showed that the tubercle bacillus in man differs from that in the bovine race. To tuberculosis science there were contributors throughout the civilized world and sanatoria were constructed nearly everywhere. The social and economic aspects of the disease were recognized and Germany went as far as to include tuberculosis among the diseases to be insured against. Life insurance companies established sanatoria for their policy holders. Industrial hygiene, including the prevention of tuberculosis, became a new science in this and other countries; popular education in the principles of the prevention of tuberculosis was given to the masses at large as well as in schools and colleges. There was reason to look forward to a time when with the progress of medical science, improved hygiene and a more brotherly feeling among all mankind, one of our arch enemies, tuberculosis, which for ages had been thought to be unconquerable, was after all to be vanquished and the prospect was even in view that the disease might perhaps disappear from the earth within the first quarter of the twentieth century.

Prior to the world war (1912), England recorded the lowest mortality from tuberculosis—105 per 100,000 population; next came Italy with 115; third, Germany with 134; fourth, the United States with 135; then France, with 185; Austria, Russia and the Balkan states, all had a far higher tuberculosis morbidity and mortality rate than the other countries. All the countries of Europe and also Japan had been looking forward to a continued, uninterrupted, and vigorous antituberculosis campaign, and our Asiatic allies, the Japanese, had even contemplated inviting us to an international tuberculosis congress after the one which was to have been held in London in 1916.

The thunderbolt which fell on August first, 1914, setting all Europe afire and spreading to all the continents of the world, put a stop to scientific research and medical and sociological labor in behalf of tuberculosis, and, worst of all, severed the brotherly bands and friendships which had been formed by our English, French, Italian, and Russian scientists with the antituberculosis workers belonging to

*Read before the American Academy of Medicine at its meeting in Atlantic City, June 9, 1919.

the nations known now as the Central Powers. These latter, Germany, Austria, Bulgaria, and Turkey, united under the leadership of the militaristic and war-intoxicated Prussian aristocracy to crush by physical force any impediment to their desire for world dominion, lost all regard for the value of human life and the intellectual, moral, and artistic treasures which had been accumulated during years of the most progressive human achievements.

How did the tuberculosis problem fare while war was in actual progress? Long before our own country entered into the strife we heard that Germany, the country which then possessed more sanatoria than any other, had started to evacuate them one by one, sending the tuberculous invalids to their homes and transforming the sanatoria originally destined, built, and equipped for the exclusive use of the tuberculous, into hospitals to take care of the wounded soldiers who returned in such numbers that they could no longer be accommodated in the regular military hospitals. Germany, formerly known for its efficiency in statistical publications, has not sent out any statistics of its tuberculosis morbidity and mortality during the war, either among its civilian population or military forces. From only one city, the city of Berlin, were reports received up to November, 1917. According to these figures Berlin had a tuberculosis mortality rate of 1.7 per 1000 in 1913, which by November, 1917, had risen to 3.1 per 1000. Now, however, the terrible increase in its tuberculosis deathrate is heard of from medical authorities, such as Professors Abderhalben, Rubner, Kraus, Kuttner, A. Czerny, and others, all ascribing it mainly to underfeeding and general physical and psychical depression resulting from the disastrous war.

At a special meeting of the united German medical societies in Berlin, December 18, 1918, at which these gentlemen made their individual reports, Dr. Hamel of the German Home Office, made the statement that tuberculosis in Germany at the end of the year 1918 had reached the same prevalence as 25 years ago; and that all the splendid results obtained by years of extensive and systematic antituberculosis campaign had been annihilated. The same authority stated that in towns of 15,000 and more inhabitants—comprising about three-eighths of the total German population—the number of deaths from tuberculosis in the year 1913 was only 40,374, while in the first half of 1918 it had already reached 41,800, which would mean more than double the death rate of pre-war times. Mr. Oswald G. Villard, of this city, the author of "Germany in Collapse," who was in Germany as recently as last March, stated that 80 per cent. of the women of Dresden had been suffering from functional disorders, due to undernourishment. Austria, Bulgaria, and Turkey have always had, as already stated, a high morbidity and mortality from tuberculosis, and to judge from the prevalence of this disease among the prisoners captured by the Allies, the increase in the tuberculosis deathrate in these countries must have been terrific.

France's tuberculosis plight was first made known to us by Dr. Hermann M. Biggs, who had been sent to France by the Rockefeller Foundation. Those of us who had the privilege of visiting France or studying there before the war, must admit that even then the disease had reached threatening proportions, but energetic measures were about to be taken to cope successfully with this serious problem when France was overtaken by the war. Accurate statistics are difficult to obtain in times like these. According to Dr. Biggs, the tuberculosis deathrate in Paris and in the cities of France which have over 20,000 inhabitants was excessive during the war, and more than twice that of New York City, which was only 1.54 per 1000 in 1918, and 1.5 per 1000 in 1919.

How serious conditions were in France in the year 1917 may be realized from Dr. Biggs' own words after his return from that country, where he had made a most careful study of the situation. He said: "The great problem confronting France is the prevalence of tuberculosis. It exists not only among the civilian population, but in the army, and among discharged soldiers. It constitutes a health problem of great magnitude and of utmost gravity. In my judgment it may readily become in the near future a real menace to the life and economic development of the French people. I say this after conference with many public officials, physicians, and citizens of France, men in high positions, and patients in the hospitals; after visits to numerous military, civil, and private institutions, to sanatoria and dispensaries for the soldiers, for refugees, and for prisoners."

Reports which have come to us more recently are fortunately much more favorable and would show that tuberculosis in the French Army has not been any more prevalent than is usually the case among soldiers and sailors; but all observers who have come in actual contact with the tuberculosis condition in France agree with Dr. Biggs as to the great prevalence of tuberculosis among the civilian population. At the meeting of the N. Y. Academy of Medicine, on November 25, 1918, Dr. James Alexander Miller reported that the tuberculosis situation among the civilian population was truly a serious one, and that although in some rural sections the mortality from this disease was comparatively low, in northern France, due to lack of food and proper care, the deathrate among children had been high. It was the graphic report of Dr. Biggs which prompted Mr. Rockefeller to send to that country a commission for further investigation and relief.

Thanks to the admirable work of this Commission which went to France in 1917 under the leadership of Professor Livingston Farrand and worked hand in hand with the American Red Cross and with the French authorities, conditions have been materially improved. A number of sanatoria, hospitals, and dispensaries for the care of the tuberculous have been created throughout France, local antituberculosis societies and committees have been formed, and a vigorous popular propaganda for the prevention of tuberculosis has been instituted. During 1918 three traveling exhibits and groups of lecturers visited ten departments, and in 141 towns of 3,000 or more population gave 875 lectures with demonstrations and exhibits. In the same period 2,115,708 pieces of printed matter, posters, pamphlets, post-cards, games, were widely distributed throughout the whole of France. A series of twenty-four articles on tuberculosis appeared in thirty-three important provincial newspapers. The

Commission's publicity material, written by French men and women, and charmingly illustrated by French artists, has set a new standard for popular public health education. (Rockefeller Foundation Report, 1919). Systematic inspection of schools and a visiting nurse system for the care of patients at home are measures about to be inaugurated.

When one compares the tuberculosis situation in France even as it was before the war with what it is to-day, one cannot help becoming inspired and encouraged by the progress made in the antituberculosis work throughout the country, and there is no standstill in this work. My esteemed teacher, Professor Letulle, very justly described the situation, some time before the armistice, when he said: "The war against tuberculosis is with us as intensely as the war against the Central Powers." Commissions have been appointed to study the question of tuberculosis prophylaxis in army and navy, and among the civilian population. Dr. F. Bezançon, of the Paris medical faculty, presented recently to the Academy of Medicine the following report:

"The 'Commission permanente de la tuberculose' is of the opinion that compulsory notification is one of the fundamentals in the campaign against tuberculosis, but that it is merely one phase of the work; the campaign against alcoholism and against insanitary dwellings should likewise command the attention of the legislators. The attending physician should register the case, and by making the notification to the health officer he does not violate professional secrecy. This dose not preclude notification by the party most interested or by the head of the family. Notification should be limited to open cases of pulmonary tuberculosis, and it should not be enforced until the prophylactic measures and necessary assistance can be realized." This assistance is surely forthcoming, for the French Senate have now voted favorably on the establishment of tuberculosis sanatoria to provide for treatment of as many as possible of the 120,000 men who had been rejected from military service on account of tuberculosis.

We know what Belgium has suffered, and while no statistics are as yet available as to the tuberculosis situation in that brave little country, it may be safely assumed that it was most serious at the time of German occupation. Had it not been for the prompt and quick relief which Mr. Hoover brought to starving Belgium, its morbidity and mortality from tuberculosis would have been even greater.

Mr. Hulot, a Belgian sanitary inspector, speaks in his report of the distressing infant mortality as the most urgent problem in Belgium's antituberculosis campaign. "The co-relation of the increase of tuberculosis with the insufficiency of food in Belgium afford a striking contrast with the conditions noted in most parts of France. Belgium, in spite of the appalling condition of affairs within her borders and staggering under the frightful ordeal of four and a half years' duration, has drawn up a program to combat tuberculosis that is modern, complete, and admirable in every detail. (Miller.)"

Prior to the war there was a low tuberculosis mortality and very little antituberculosis work in Belgium. There were virtually no sanatoria and the few general dispensaries to which tuberculous patients were permitted to go were conducted by physicians privately. Col. Le Page and Capt. Réné Sand, who visited the United States recently as members of the Belgian commission, are determined on their return to inaugurate an effective antituberculosis crusade throughout that country. The deep interest and enthusiasm these gentlemen manifested in our own tuberculosis institutions and methods is a guarantee of a decisive antituberculosis propaganda in Belgium to be followed by effective curative work.

According to the report from Mr. Seymour H. Stone of Boston, who has been in charge of Red Cross work in the province of Genoa, Italy, between 40,000 and 60,000 Italian soldiers have contracted tuberculosis while in Austrian prisons. This is indeed a fearful percentage and gives an appalling picture of the food situation in Austria during the war, not to speak of the unsanitary housing of the war prisoners. From the general report issued by the Commission for Tuberculosis of the American Red Cross, we learn that the deathrate from tuberculosis in Italy between the years 1909 and 1913 was only 115 per 100,000; during the last two years of war the tuberculosis deathrate in some of the cities was nearly four times as much. In Florence the mortality rate from pulmonary tuberculosis reached the enormous figure of 403 among 100,000 population in 1918. In Bergamo the rate was 408 in 1918 as against 198 in 1914. According to the report, the indications are that the spread of tuberculosis has been equally serious in the rural districts. The American Red Cross tuberculosis unit was sent to Italy in October, 1918. The Commission was headed by Dr. William C. White of Pittsburgh with Dr. R. H. Bishop, Jr., of Cleveland, as associate and Louis I. Dublin, Ph.D., as statistician. It undertook the inauguration of an educational program for the prevention of tuberculosis in cooperation with the Italian authorities and it seems to be accomplishing excellent results by doing work in Italy similar to that which had been done in France. While the hygienic conditions prior to and during the war cannot be considered superior to that in France, the milder climate in the greater part of Italy and particularly the greater number of sunny days, were doubtlessly responsible for a smaller tuberculosis morbidity and mortality than would be the case were it less favored by the natural conditions which are conducive to the prevention and cure of tuberculosis.

Valuable information concerning the tuberculosis situation in that country has come to me through the courtesy of Col. Homer Folks, former charity commissioner of New York City, who has only just returned from an extensive visit to Italy, Greece, and Servia, where he investigated the general economic and sanitary conditions of those stricken countries. The tuberculosis situation in all these countries is exceedingly grave. He reports an increase of tuberculosis mortality of 17 per cent. throughout Italy from 1914 to 1916, and a further increase in the cities of 12 per cent. in 1917. In Greece, matters seem to be even worse. There had been a death rate of 1 in 6 from tuberculosis in Athens before 1914, which, owing to war conditions, has undoubtedly increased, although exact statistics were not available.

When one considers the terrific sacrifices England

and her colonies have made in men, material, and finances in the war, one cannot but wonder at the relatively favorable tuberculosis-situation in the British Empire. But the British Journal of Tuberculosis freely admits that in England also, tuberculosis has become more prevalent and damaging, and has claimed a larger number of victims. According to Dr. Halliday G. Sutherland, the deathrate from pulmonary tuberculosis since 1914 has risen 12 per cent. Here as everywhere else, the war resulted in a diminution of the activities in the tuberculosis movement, but with that energy characteristic of the British race, England and her colonies are working hard to meet the new problem. During a recent visit to Canada I was privileged to inspect the new and splendidly located Laval Hospital for the tuberculous at Quebec; and in Montreal I was shown a magnificent site, formerly occupied by a religious order, which that city has purchased for the erection of a large modern tuberculosis hospital-sanatorium for its consumptive poor. From a very interesting communication, entitled "How Canada Is Meeting the Tuberculosis War Problem," by my good friend Lieut. Col. Jabez H. Elliott, of Toronto, (Transactions of the National Tuberculosis Association, 1918), we learn of the thorough work which is being done by our neighbors to the north to meet the needs for hospitalization, vocational education, and pensions for her tuberculous soldiers. No less than 19 sanatoria are receiving the Canadian tuberculous heroes, eager to restore them to health and earning capacity. Only a few days ago I received a letter from Sir William Osler, who, in discussing the tuberculosis situation in England, says: "All goes well here and I hope we will get the tuberculosis problem settled ere long on national lines."

Less happy news comes to us from our smaller Allies, Roumania and Servia. Pathetic is the tuberculosis situation in Roumania, but more so it is in Armenia and Servia. No exact statistics are available but we have heard and read enough of the indescribable sufferings which poor Armenia had had to endure while under Turkish dominion and during the war. All that tends to the propagation of tuberculosis and makes cure impossible, such as privation of food and shelter, exposure to the inclemency of the weather, to excessive cold and excessive heat, the herding together of masses in filthy and unsanitary houses, mental anguish and physical suffering, the Turks took good care to prepare for the few million Armenians whom they had not murdered outright.

In Servia, which held the enemy forces at bay for 14 months, the people have perhaps suffered from tuberculosis more than any country of the Allied or Central Powers. Col. Homer Folk estimates that the Servian population is now 25 per cent. less than it was at the outbreak of the war. The mortality from tuberculosis in the north of Servia, including the city of Belgrade, which was already high before the war—324 per 100,000—and in 1912, in Belgrade, 720 per 100,000, has now risen in that city to 1,483 per 100,000, according to an Austrian report of 1917. Dr. Rosalie Slaughter Morton, who has only recently returned from Servia, likewise described the tuberculosis situation to me personally as simply appalling. Men, women, and children were dying by the thousands from this disease. Out of 14,000 Servian prisoners who were returned to their home country after the armistice, 6,000 had contracted tuberculosis, and in the new Czecho-Slovac republic conditions seem to be fully as bad. Dr. J. C. Beck, of Chicago, who has been with the Czecho-Slavs as a military surgeon, reports to me that tuberculosis in Prague among children alone has increased to a veritably alarming degree. In 1914 the tuberculosis morbidity rate in Prague among children was 3 per cent.; in 1919 it was 29 per cent. These figures were given to Dr. Beck by Dr. Alice Masaryck, the president of the Czecho-Slovac Red Cross, who is the daughter of the president of the new republic.

From the newly created Polish republic there comes sad news concerning the tuberculosis situation. Thus it was stated by Consul General C. Buszczynski, the head of the Polish mission which recently arrived in this country, that in Eastern Poland there existed in April of this year no less than 500,000 cases of tuberculosis.

Russia, once our Ally, is to-day a country without an ally and without a government. Its homes are devastated and millions of men, women, and children are on the brink of starvation, not because of a foreign war but from the destructive forces of its own people, misguided by a few fanatics. These leaders cannot, or will not, see that order, work, and brotherly love are alone capable of producing an ideal government and a satisfied people. How many tuberculous cases have developed during the last five years in Russia, how many will develop there before peace and order again reign supreme and the people work for instead of against each other, is difficult to even imagine. There is little doubt, however, that since Russia in peace times was known to have the greatest morbidity and mortality from tuberculosis among all civilized nations, its present condition of chaos will multiply the death rate from this disease many times, which to overcome will be a staggering problem for the men who will succeed in saving Russia and making a peaceful republic there.

We now come to our own country which of course has suffered the least of all the great nations involved in this world war. The tuberculosis situation in the United States, as compared with other countries, has seemingly not been so greatly affected. Thanks to the most thorough method of examination and reexamination of all men who had volunteered or were drafted into the Army or Navy and also of the candidates for officers, a relatively small amount of tuberculosis developed in our fighting forces. That in spite of this careful examination a certain number of tuberculosis cases should develop among over two million fighting men in the U. S. Army and Navy was inevitable. But here again, thanks to the foresight of Surgeon General Gorgas, his successor Surgeon General Ireland, and the Surgeon General of the Navy, our federal government has done and is doing its utmost. Six government sanatoria with a capacity of 6,000 patients are now in operation. These institutions are located at New Haven, Conn.; Otisville, N. Y.; Spartanburg, S. C.; Oteen, N. C.; Denver, Colo.; Fort Bayard, N. M. Under the direction of Surgeon General Braisted, of the Navy, an excellent institution for tuberculous

sailors is in operation at Fort Lyon, Los Animos, Colo., and the United States Public Health Service operates an institution for several hundred patients at Fort Bayard, N. M.

In accordance with Public Act 326, approved March 3, 1919, entitled "An act to authorize the Secretary of the Treasury to provide hospital and sanatorium facilities for discharged sick and disabled soldiers, sailors and marines," the bureau is authorized to send to any relief station of the Public Health Service any discharged sick or disabled soldier, sailor, or marine, army or navy nurse (male and female), provided that the disability for which he seeks treatment is due to illness (including tuberculosis) or injury incurred previous to discharge from the military forces.

Thus, to provide for additional numbers of soldiers and sailors whose disease is already diagnosed as tuberculous, or may be so on their return home, Surgeon General Blue of the United States Public Health Service is contemplating a chain of tuberculosis hospitals all over the country. The sum of $7,000,000 has already been appropriated by Congress for that purpose. It is planned to erect the hospitals on Government property in the following cities: Boston, Mass.; Hill, Mass.; Chicago, Ill.; Cleveland, Ohio; Detroit, Mich.; Evansville, Ind.; Louisville, Ky.; Norfolk, Va.; New Orleans, La.; San Francisco, Cal.; Seattle, Wash.; St. Louis, Mo.; Wilmington, N. C.; Fort Slocum, Mo.

How very thorough the work is which is being done for our tuberculous soldiers may be learned from a letter sent by Surgeon General Ireland to all army surgeons and hospitals defining the policy of the war department in regard to the disabled United States soldiers:

"It is the plan of the department to retain, so far as practicable under military control, for the purpose of medical and surgical treatment (a) officers and soldiers suffering from acute diseases or acute exacerbation of chronic diseases or unhealed lesions; (b) officers and soldiers suffering from communicable diseases, or who are 'carriers,' whose discharge would be a danger to the civil community; (c) officers and soldiers suffering from disabilities incurred in the line of duty which are correctible within their term of service or enlistment; (d) officers and soldiers suffering from chronic or permanent disabilities incurred in the line of duty, which are susceptible of improvement by measures for mental or physical reconstruction designed to fit them for return to their home, for the resumption of their former vocations, or, with their consent, for the industrial opportunities or the training courses provided by the Federal Board for Vocational Education. In the accomplishment of this policy it is the intention to restore officers and soldiers, who are held in service as provided above, to health and function as fully as possible, considering the nature of their disabilities, the limitations of the military service, and the other provisions which the Government has made for the care of the permanently disabled.

"Instructions as to specific cases provide that cases of tuberculosis should be kept under treatment in military hospitals until the disease is arrested, or until it is ascertained that they are progressive in type or incurable."

During a recent tour across the continent lecturing on the "Prevention of Relapses in Cases of Arrested Tuberculosis Among Soldiers and Sailors" (Journal A. M. A., Feb. 22, 1919, and additional notes in same Journal, June 21), I visited a most splendidly equipped Government tuberculosis hospital at Denver, Colo., known as the "Recuperation Hospital." All sorts of occupations which the cured tuberculous soldier is hoped to be able to pursue, are there taught by experts in the rehabilitation and reconstruction of the diseased and disabled. Similar work is done in all the other Government tuberculosis hospitals.

Because of the 62,000 cases of tuberculosis discovered among the young men of draft age when examined by the medical members of local boards and the 20,000 more who had to be rejected after they had arrived at the training camp because of distinct symptoms of that disease, the National Tuberculosis Association, with the help of the Surgeon General's office, has inaugurated a follow-up system and it is hoped that thereby many cases will ultimately be reached and properly treated.

While it is impossible at this time to state to what extent the fearful influenza epidemic of the past year has increased the number of tuberculous individuals among the civilian population, the opinion has been expressed by many general practitioners and specialists throughout the country, which from my own observation I certainly feel inclined to confirm, that the unusually severe influenza epidemic is responsible for the development of many latent and formerly unrecognized cases into active tuberculous disease.

The educational, preventive, and therapeutic tuberculosis work among the civilian population in the United States has really not suffered much because of the war. To the best of my knowledge, in not a single institution were civilian patients discharged to make room for tuberculous soldiers or sailors, and the building of new sanatoria has not ceased in spite of the war. Popular tuberculosis education has gone on almost uninterruptedly in the United States. The anti-tuberculosis activities of most of the State and city health departments are increasing more than ever. Thanks to the help extended to us by the Red Cross, more tuberculosis committees and State tuberculosis societies have been established and are enabled to do more intensive work. Lastly, the membership of the National Tuberculosis Association is constantly on the increase.

Dr. Philip P. Jacobs, the assistant secretary of the executive staff of the National Tuberculosis Association, has been kind enough to furnish me with the following figures concerning the association's activities and the present status of the anti-tuberculosis situation in the United States. Up to June first the Society had a membership of 4066; at the present time there are approximately 600 hospitals and sanatoria for the tuberculous in the United States. Since some hospitals take early cases, and some sanatoria also admit advanced cases, it is difficult to distinguish between the two kinds of institutions. It is equally difficult to ascertain accurately the number of open-air schools, for the reason that many people include fresh-air classes and open-window rooms among the open-air schools. Dr. Jacobs estimates the institutions where instruc-

tion is given in the open air to be between 1000 and 1500 in the United States. Of typical preventoria, such as those in Framingham, Mass, and Farmingdale, N. J., there exist about a dozen, and perhaps twice that number of preventoria are working in conjunction with tuberculosis hospitals. There are about 500 tuberculosis dispensaries in operation in the United States. There are approximately 1400 tuberculosis associations and committees, including a well organized and businesslike State association in every State, and each has a full-time secretary. There is also an association with a full-time secretary for practically every large center of population. The Red Cross appropriation of $2,500,000 is being distributed as follows:

(1) Ten per cent. is set aside for the budget of the National Association, amounting to an Emergency or Missionary Fund...	$250,000
(2) Each State association is guaranteed an amount equal to the gross proceeds of the seal sale for 1917, the aggregate of these amounts being, approximately	1,819,000
(3) The remaining sum, amounting to approximately ..... is being distributed to the States on a pro rata basis; the ratio of each State being determined by the proportion of members enrolled in each State in the Red Cross Christmas Roll Call of 1918.	431,000
(4) Appropriations for the Missionary Fund are being made to needy States, particularly the weaker or more recently organized ones, on specific request of the National Association.	

A rather new feature of State activity was inaugurated by the New York State Health Department, under the leadership of Prof. Hermann M. Biggs. Free clinics are held throughout the State to which tuberculosis experts are sent to aid the local physicians in early diagnosis of tuberculous disease in children and adults, and in the installation of proper hygienic, dietetic, and therapeutic measures. This method has been helpful through the discovery of many early unsuspected cases of tuberculosis. By placing these patients under proper treatment at the right time, these popular clinics are helpful in saving many valuable lives. Similar State clinics are now in operation in Massachusetts and Vermont. It was my privilege to hold some of these clinics for the Health Department of the State of New York, and it was indeed inspiring to see with what wholeheartedness the local physicians entered into this work for the common good. It gave a splendid proof of their altruism and genuine desire to aid the State department in an effective antituberculosis campaign.

Encouraging and hopeful as are these manifold activities in our own country, we must not stop here. While much is done, there is still more to do. More sanatoria and hospitals for the poor, as well as for the moderately well to do, workshops and work colonies for the tuberculous invalids (partially recovered), more open air schools, more preventoria and similar institutions are needed, as well as extensive educational propaganda. We must still look to our generous-hearted wealthy fellow citizens for help in establishing and maintaining such institutions. Municipal, State, and even Federal funds, do not suffice alone to cope with the problem. But by whatever is done now through public means or private philanthropy in preventing and curing tuberculosis, we all will be the gainers in the end. The commonwealth will have fewer paupers and more breadwinners, and we will all be a happier and healthier people.

And now, after this hasty glance at the tuberculosis situation before and during the world war in our own country, the countries of our Allies, and the countries of the Central Powers, what is it going to be necessary to do to cope with this enormous problem, which now more than ever is really a world problem? It has been suggested that Geneva become the general Red Cross center from which all relief for nations in distress, owing to disease or physical disasters, should be directed. I hope that a great International Bureau, composed of tuberculosis experts from all over the world, may form a part of the great Red Cross headquarters. From there the best that is known in prophylactic measures should be taught to all the nations in need of advice and guidance in popular antituberculosis propaganda. Experts in the construction, equipment and management of tuberculosis hospitals and sanatoria, preventoria and dispensaries, work colonies, factories, and workshops for tuberculous invalids (after the model of the Altro Shop of New York City),* should form a subdivision of the International Tuberculosis Bureau; and last, but not least, through its medical and scientific division, all the accumulated knowledge and all the new discoveries regarding phthisiotherapy, including early diagnosis and the prevention of relapses in tuberculosis, should be made available to all mankind.

The financial aid necessary to carry out educational and therapeutic measures to combat tuberculosis in our own and in countries too poor to do it for themselves, or only able to do a part, can best be distributed through the Red Cross headquarters. Because of their machinery they will be better able to judge how much and where the money for tuberculosis relief work can and should go.

The American Red Cross has its national headquarters in Washington, D. C.: The President of the United States, Woodrow Wilson, is also the president of this organization; the Hon. William H. Taft and Mr. Robert W. De Forest are its vice-presidents; Prof. Livingston Farrand, M.D., is the chairman of the executive committee. The secretary-general of the International League of the Red Cross Societies is Dr. William Rappard, Professor of Political Economy of the Universities of Harvard and Geneva, with headquarters in the latter city. The office of the National Tuberculosis Association

*This shop is occupied exclusively by ex-sanatorium patients. They work two, four, six, or eight hours a day, whichever amount in the judgment of the supervising physician they may do without any fear of relapse. If they do not earn sufficient to support their families, philanthropic associations supplement the difference. Thus all anxiety is relieved from the patient's mind. Such a factory or workshop, even though it may not be self-supporting, will pay in the health restored and self-respect regained. It saves the community the cost of relapse, as well as a large expenditure for relief. Under proper management and on a sufficiently large scale, such factories or workshops may be entirely self-supporting. All work is done with the windows wide open, in winter and in summer, and under strictest sanitary conditions in general. (For further details concerning this unique, humane and yet businesslike enterprise see Hochhauser: "Discharged Tuberculous Patients in Factory Work," Transactions of the Nat. Tub. Ass'n, 1918, p. 456.)

is located at 381 Fourth Avenue, New York City. The executive office staff consists of Charles J. Hatfield, M.D., the managing director; Philip P. Jacobs, Ph.D., and Donald B. Armstrong, M.D., as assistant secretaries. An annual Red Cross seal sale for the benefit of the antituberculosis work in the United States is conducted by this office. Dr. Armstrong is also the director of the Framingham Health and Tuberculosis Unit. This health unit, which came into life through the donation of $100,000 by the Metropolitan Life Insurance Company, demonstrates what may be accomplished in a community by the strictest sanitary, prophylactic, and curative methods in preventing and curing disease, particularly tuberculosis. The work is done by a thorough coordination of public and private agencies. The value of such "health and tuberculosis demonstration" must be obvious, and offers a great field of philanthropy to wealthy individuals and corporations.

Valuable information concerning general antituberculosis propaganda and the progress of tuberculosis science can be gathered from the following publications.

The American National Tuberculosis Association publishes as its official organ the *Journal of the Outdoor Life*, of which Dr. Philip P. Jacobs is the managing editor. The air of this journal is "to be helpful to persons seeking health by an outdoor life, and particularly to disseminate reliable information looking to the prevention of tuberculosis." In addition to this widely read journal, the association publishes also the "American Review of Tuberculosis," with Dr. Edward R. Baldwin of Saranac Lake as editor in chief, and Dr. Allen K. Krause of Baltimore as managing editor. This periodical is mainly devoted to the discussion of the purely medical and scientific aspects of tuberculosis.

After such general suggestions there are, of course, an infinite number of other things which arise in one's mind when viewing the actual situation. There is the question of birth control in devastated countries, where there are still thousands of people with little food and poor shelter. In regard to this I am willing to subscribe absolutely to what was recently said by Dr. C. K. Millard, health officer for Leicester, England. He writes as follows:

"The question of the birth rate is intimately bound up with that of birth control. It is unfortunate that scientific study of the subject has been hitherto neglected. Owing to the supposed moral stigma, many had tabooed it, and it is only quite recently that unbiased discussion had become possible. The subject is of special interest and importance at the present day through conditions arising out of the war. In many parts of Europe the social conditions of the people, with starvation staring them in the face, without proper clothing or shelter, with civilization itself broken down, are deplorable in the extreme. It appears eminently desirable that rigid birth control should be practised in those countries, and probably in others also, if acute maternal suffering and terrible infant mortality are to be avoided. The best thing for the people of those countries to do is temporarily to stop having children, so far as it can be avoided, until happier and more prosperous times arrive. It seems to be taken for granted in most countries that rapid increase in population is needed in the national interest, and that a stationary population would be disastrous. No doubt this sentiment is really based on militarist considerations, and in the past, when such considerations were vital, it might have been wise to encourage it. But now, with the international situation fundamentally altered, and with the League of Nations (whose special function it would be to safeguard the nations with small populations), it is time to reconsider our attitude. International competition in birth rates is to be avoided, just as was competition in armaments. There are certain countries which are already "saturated" as regards population, in the sense that any further increase would not tend to increase the happiness or prosperity of the inhabitants. Wherever that point has arrived, or is nearly at hand, birth control must be regarded as the proper remedy, and as greatly preferable, in most cases, to emigration. The case of England is complicated by the fact that she is the mother country of an empire. Many people would agree that the population of the British Isles is large enough, but they wanted to see her great colonies filled up with an all-British population. No doubt this is very patriotic, from the standpoint of conditions before the war; but from the point of view of the League of Nations they ought to regard their colonies as the natural outlet for the surplus population of all European countries. It is so necessary for the peace of Europe that such an outlet should exist that they need not be in any hurry to see those territories filled up. As to the question of practical methods, physicians have not given it sufficient attention to enable them to speak very authoritatively. Certain physicians, with obviously a strong bias on moral grounds, have condemned all methods as highly injurious, but the bishops, in a special report on this subject presented to the Pan-Anglican Conference in 1908, have seized an isolated medical opinion of this kind and used it as though it were the considered verdict of the medical profession.

"To ascertain what is the real opinion of the profession of the present day, Dr. Millard has recently issued a questionnaire to medical practitioners, and from some eighty replies received he is quite satisfied that the great majority of the profession does not regard birth control as necessarily injurious." (London Letter, March 27, 1919, to Journal of the A. M. A., April 19, 1919.)

In spite of this sound reasoning and advice, many tuberculous mothers will bear children, and if the mothers do not survive, some of the children may. These and other children who have contracted tuberculosis it is the duty of the physicians to endeavor to save. Maternity sanatoria, where the mother with an early tuberculosis may stay before and a sufficiently long time after her confinement to give her a reasonable chance for recovery, must be created. Tuberculosis dispensaries to act as clearing houses for all kinds of tuberculous afflictions, and attached to them a corps of visiting nurses; preventoria, where the strongly predisposed child may have a chance to overcome its predisposition; children's sanatoria, where the young having pulmonary, glandular, and bone tuberculosis may be treated for their afflictions; favorably situated sanatoria for the early cases, hospital-sanatoria near

large centers of population for the more advanced cases; special institutions for post-sanatorium treatment, where the arrested cases can be prepared to resume their physical labor and general occupation without danger of relapses; special sanitary workshops for vocational training of tuberculous invalids and ex-patients; horticultural and agricultural colonies for the tuberculous able and willing to pursue these open-air occupations; and lastly, open-air schools for tuberculous children and tuberculous teachers constitute the chain of institutions which an enlightened community must provide in order to cope effectually with the tuberculosis problem.

It goes without saying that a nation's antituberculosis crusade must include all the other modern measures which this world war has taught us as being necessary in preventing disease (particularly tuberculosis) and in increasing the physical and mental well-being of the masses, such as child welfare work, compulsory general education, including practical lessons in hygiene from kindergarten to university, repeated periodic physical examination of all people, and the institution of remedial measures to correct defects. A three-months' physical training of all girls between the ages of 16 and 18 and a six-months' physical training of all boys between the ages of 18 and 20, to make the physique of these future fathers and mothers as nearly perfect as possible, would be an additional assurance of a healthier and happier future race. However, to obtain the goal, this course of physical training should be accompanied by a series of lessons teaching the future parents of the nation the obligations of sound father- and motherhood and the proper raising of physically, mentally, and morally sound children. No marriage certificate should be issued without both partners presenting a certificate of health by a medical man or woman of recognized professional standing.

To all this, of course, must be added sanitary housing of the masses, industrial hygiene, judicious anti-alcohol measures, and opportunity for healthy labor and occupation which will enable the man and woman to earn a good livelihood without being deprived of sufficient rest and recreation. Child labor must be done away with if we wish to do away with tuberculosis. All this should be done by an enlightened nation, State, or community, but surely it may only be done by a prosperous one.

And now we may well ask, who is to enlighten the people of the countries of our Allies and those of the Central Powers, where general hygiene and the knowledge of the prevention of tuberculosis have been, heretofore, confined to the few among the wealthy classes and perhaps to the medical profession alone? Who is to help the communities which have faced starvation, misery, and poverty for well-nigh five years, to become prosperous once more? This work must devolve upon us, the most favored of the belligerent countries, the one which has suffered least from the great white plague during the war, and which, in spite of all the great financial sacrifices made, is still the most prosperous and best able of all the civilized nations to help the countries now so sadly afflicted with the great white plague to obtain food, shelter, and clothing, to enter again upon the pursuits of health and happiness. Regarding the enlightenment of these nations on the subject of the prevention of tuberculosis, I wish to say, not in the spirit of boastfulness, but rather in humility and gratitude that our country is to-day, thanks to the philanthropy of generous-hearted citizens, to wise statesmanship, and the devotion of many public-spirited men and women, best able to enlighten and instruct in the prevention and treatment of tuberculosis, which is now the curse of so many nations as a sequel of this world war. Thousands of the noblest of our sons have made the supreme sacrifice that others might be happy and free. They are calling to us now to do our duty here, and everywhere where there is misery, suffering and want. We must help our own afflicted as well as the tuberculous of all nations, and those of us who cannot render personal service, but are able to help financially in the solution of this grave world problem, can best do so by supporting the work of the local, national, and international Red Cross societies.

Never in the history of the world has there been such an opportunity to show the greatness of our nation in heart, mind, intellect, and willingness to help our afflicted brethren and sisters throughout the world. To the often quoted biblical question concerning our responsibility toward our fellowman, there can be but one answer from the true American, namely: "Yes, I will lend him a willing hand, teach him what I know, and give what I can, for verily I am my brother's keeper."

EPISEOTOMY:

ITS RELATION TO THE PROPER CONDUCT OF THE PERINEAL STAGE OF LABOR.*

By CHARLES G. CHILD, Jr., M.D.,

NEW YORK.

When the presenting part of the child approaches the perineum the rôle assumed by the one in charge of the case, that up to this time may have been entirely passive, becomes more active. It is just at this stage that the medical attendant too often forgets his responsibility, he is apt to lose sight of his full duty to the patient in his new found joy at what he hopes is about to be the successful termination of the case that, up to this time, may have harassed him with doubts and uncertainties, prolonged over many hours of tedious waiting. He now urges the woman to redoubled efforts, and often neglects to administer an anesthetic, fearing thereby to retard the pains and further prolong his agony. As a result the patient's suffering is greatly increased, and her future usefulness in life is often impaired by a serious traumatism of the pelvic floor.

From now on I shall endeavor to sketch for you the various points of procedure that I have found of particular service at this stage. As the head approaches the perineum, the danger point in the stretching of the levator muscles begins. Whether they will be equal to the situation and allow the birth of the child without sustaining permanent injury, is a question that can never be decided with certainty until after the birth has occurred. Many

*Read before the City (Charity) Hospital Alumni Society, March 19, 1919.

times the prolonged dilatation, where perineal stretching is unduly delayed, results in a paralysis of the muscles that is just as disastrous as their actual tearing would be, giving rise to a condition more difficult to correct subsequently than the actual tearing would have been; therefore, do not unnecessarily keep the head on the perineum with the idea of securing sufficient dilatation to prevent laceration. Many times a solution of continuity occurs that shows no evidence externally. I have seen the vaginal wall, the levator muscles, and the sphincter muscles torn completely without any laceration showing externally, and this has happened in cases where only moderate bulging was observed.

When the head has advanced sufficiently to begin the separation of the vulva is the time to open the vagina between pains, as the head recedes, and to inspect its walls carefully. Any tearing of the mucous membrane, even though slight, is an indication that such tears will, in all probability, later involve the deeper structures.

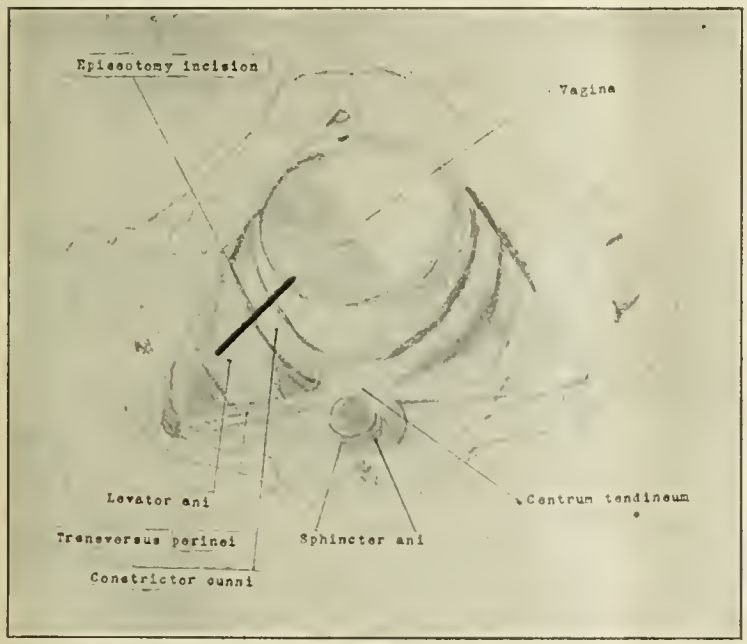

FIG. 1.—Showing line of incision in relation to the anatomical structures.

We have now the choice of two procedures for the preservation of the perineum: The first is the time-honored one of holding back the head with each pain until we think that a sufficient degree of stretching has been obtained to allow its birth without laceration; the second is that of sufficiently enlarging the opening by an incision. The first method, I think you will agree with me, is more or less uncertain; the second, when properly performed, I believe to be absolutely certain.

The operation of episeotomy is an old one, but, like many old things, often forgotten or derided. It is an operation well within the ability of the general practitioner. It shortens the perineal stage of labor, saves the perineum, and many times, in breech deliveries, the life of the child as well. It converts a breech extraction in a primipara into as easy an affair as in a multipara—if I may be allowed to use the word "easy" in conjunction with such a formidable subject as breech delivery.

To bring more clearly before you the value of episeotomy, I will here present briefly some clinical data derived from 153 consecutive deliveries in private patients. Many of them were cases seen in consultation, and this accounts for the high percentage of abnormalities encountered. In the series, episeotomy was performed 63 times. In three of these double episeotomy was necessary; once for a very large, hard head in an elderly primipara, and the other two with a normal-sized baby, but an abnormally small and rigid outlet. In the single cases, the incision was made on the right side, with three exceptions; these where numerous varicose veins of the vulva contraindicated the use of the right side, and I was able to secure on the left an area for the incision comparatively free from any formidable varicosities.

Forceps was applied 28 times. There were four breech deliveries, where the extraction was greatly facilitated, as I have pointed out above, by the episeotomy. One of these patients was a multipara and the other three were primiparæ. There were four cases of eclampsia, where a rapid perineal stage was highly desirable. In five cases pituitrin was used successfully for the existing uterine inertia.

In the whole series of 166 cases 112 were primiparæ, 54 multiparæ. Of the 54 primiparæ who were episeotomized, three failed to unite by primary union, two of them being septic at the time of delivery. There were three cases where some laceration occurred as well, because the incision had not been made large enough, but there was no complete or even extensive tear in the total series. Only nine of the multiparæ required the operation, one a breech and three forceps. Of the 58 primiparæ not episeotomized, 18, or 31 per cent., sustained lacerations, in spite of all due care, and involvement of the anal sphincter occurring twice.

In two cases the child was expressed by pressure on the fundus. There were six cases of occiput posterior positions, two of which were rotated with the hand, and four with forceps. In all but three cases the episeotomy incision healed by primary union. In three cases an error in judgment was made in performing the episeotomy, which was not sufficiently extensive, so that there was some perineal laceration as well. These perineal lacerations were only slight, there being no case of sphincteric laceration. One woman had been previously operated upon for prolapse with extensive perineal laceration. In this the episeotomy saved the repair work of three years before. In one case a complete tear had been repaired two years before the delivery. Here the episeotomy likewise prevented the destruction of the previous repair work.

Summary.—The operation of episeotomy consists of enlarging the outlet of the birth canal by an incision made with a knife, or preferably with scissors. The site of the incision is on one side of the vulva, and should go through the skin, subcutaneous and adipose tissue, down to the levator muscle. The division of the muscle should be carried to a point just sufficient to allow the birth of the head. The extent necessary is gauged as the head advances

with each pain. The division of the fibers progresses hand in hand with the pressure of the head, until the proper point has been reached. In some primiparæ, in whom the introitus is over small, or the head over large, bilateral episeotomy

Fig. 2.—Perineum bulging; incision about to be made.

may be necessary. In breech extractions, where plenty of room is so often necessary for the release of extended arms, or to incise a cervix that has contracted around the neck of the after-coming head, no chances should be taken with a small incision.

The suturing of the incision after delivery offers no particular difficulty. Interrupted silkworm-gut sutures are the best, and these should be passed deeply from without inwards, taking up all tissue as far as the vaginal mucosa. This latter is then united by a continuous suture of No. 2 chronic catgut. All sutures can be introduced while waiting for the expulsion of the placenta when the patient is still under the anesthetic, and their introduction is greatly facilitated by the placing of a medium sized laparotomy pad in the vagina to prevent the obstruction of the field of operation by the blood coming from the uterus. These sutures ought not be tied, however, until after the delivery of the placenta in case it should be adherent, making a manual removal necessary.

Fig. 3.—Area of incision; all sutures introduced, ready to tie.

Though many good authorities give episeotomy a low rating, I warmly approve of it, and can heartily recommend it as a most valuable operation for the general practitioner as well as the specialist.

THE EXPLANATION AND TREATMENT OF THE EFFORT SYNDROME, NEUROCIRCULATORY ASTHENIA (SOLDIERS') IRRITABLE HEART.*

By GEORGE EDWARD BARNES, B.A., M.D.,

HERKIMER, N. Y.

During the war there were published many articles on the important and frequent disease variously named the irritable heart of soldiers, the effort syndrome, neurocirculatory asthenia, etc. In regard to the etiological pathology and fundamental nature of the disease most of these articles were entirely in the dark and only a few of the latest ones exhibited a slight insight. I wrote to several of the authors of these articles and to the Surgeon General, calling attention to former articles† of mine in which the fundamental elements of this syndrome are set forth, and presenting further relevant ideas. It is particularly in response to a hint from the Surgeon General, received several months ago, that I present this communication. It has been delayed chiefly because I felt that if my former articles were properly studied and digested there would not be need of further presentation. However, a definite and direct treatment of this subject may be of assistance, but the reader should become acquainted with my former articles in order to comprehend this one properly.

The effort syndrome is one of the many manifestations of neurasthenia. There is no wonder, therefore, that it has not been understood. Even Sir James Mackenzie not long ago openly declared that he did not know what neurasthenia is and he accordingly called it "the X disease". Such is still the state of knowledge of nearly all medical men even to-day, several years after the publication of my articles. If we realize that *all* people whom we treat have brains and minds and that, whatever may be their natural endowment and intellectual state, they experience emotions and that, unless they are abnormal, they are capable of suffering from severe affective diseases, we must realize the very great importance of a very thorough knowledge of these diseases. Not only do affective disturbances and neurasthenia in general constitute a very large part of the cases seen by most doctors of medicine (although they do not yet recognize the fact), but these disturbances also often complicate the picture of most other ailments. They are almost perpetually present. Indeed, when medical men become familiar (as each is in duty bound to do) with normal psychology as set forth in some book which does not hold the James-Lang theory of the emotions, and when they become familiar with pathological psychology, particularly as set forth in my articles, a new era will have dawned in the practice of medicine and in human health, happiness, and efficiency. No human being can be scientifically attended for any ailment whatsoever

*Read before the Medical Society of the County of Herkimer, June 3, 1919.

†"Affective Activity, Emotions, as the Cause of Various Neurasthenic Bodily Diseases," *N. Y. Med. unless due account is taken of these profoundly human and very prevalent conditions. A correct knowledge of these things is also the only specific cure or antidote for that fashionable bugaboo—so-called intestinal autointoxication—which has been working havoc with scientific medicine.

The anatomical parts involved in the effort syndrome are, from the standpoint of etiology, the so-called "sympathetic nervous system" and that part of the brain concerned in the development and propagation of "violent" affective currents and are, from the standpoint of the fully developed disease, essentially the whole body, particularly the arteries, heart, stomach, and intestines.

The affective portions of the brain and the sympathetic nervous system are excessively irritable to all stimuli, as is so evident, *e.g.* in the use of certain drugs, as epinephrin and cocaine. The pathologico-physiological forces that are active are stimulating currents originating in the "violent" affective centers of the brain and in the structures of the sympathetic nervous system.

The signs and symptoms of the disease are caused *directly* by these pathological currents stimulating to excessive activity certain organs, particularly the arteries and heart, and *indirectly* by the effect which this excessive activity has on other organs. To illustrate, these currents stimulate the arteries and heart to excessive tonic contraction and this contraction in turn causes such symptoms as breathlessness, headache, giddiness, fainting, precordial pain and hyperesthesia, nausea, and even vomiting. By the way, although contracted arteries are doubtless the most marked sign of the disease I have not seen it mentioned in any article to date.

I wish particularly to call attention to the fact that the effort syndrome occurs in three forms, which may be classified as follows: (1) Primary; (2) Secondary or reactionary: (*a*) Following nervous prostration or less severe states of pathetic emotion; (*b*) Following other serious diseases.

In the case of the primary group currents of violent affectivity are aroused by certain ideas, with or without physical exertion, then pass through the sympathetic nervous system and cause certain activities in the organs of the body, as increased frequency and tonicity of the heart, excessive contraction of the arteries, excessive secretion of epinephrin, etc. Of course, corresponding effects follow such ideas and efforts normally, but in this disease there has been such great expenditure of energy by the oft-repeated, prolonged, and excessive affective currents along the same channels that the anatomical parts involved have become weakened and excessively irritable and excessively responsive to stimuli. The severity of the disease in this group varies from very slight to very marked.

In group (2) subdivision (*a*), the mechanism is different. Previous to the development of the disease in this subgroup pathetic affectivity dominates the whole being, mildly or severely, even to the extent of complete nervous prostration. But when from this condition recovery begins, excessive pathetic affectivity subsides and the hitherto suppressed "sympathetic" nervous system and the violent affective apparatus in the brain spring into spontaneous activity, which soon becomes extremely severe in convalescence from nervous prostration. This form of the disease is essentially a rebound from the (relaxed) condition of the body caused by pathetic affectivity. It is a part of a larger entity.

Group 2, subdivision (*b*): During any severe general disease, *e.g.* a fever, the nervous system is of course much weakened and when recovery begins there takes place, similarly as in the preceding subgroup, a spontaneous excessive activity of the "sympathetic" nervous system and the violent affective apparatus in the brain, a rebound, producing the excessive activity in the organs of the body and giving rise to the symptoms.

Arrhythmical disorders of the heart beat, especially extrasystole, appear frequently during convalescence from both subdivisions of the secondary group.

The foregoing description indicates the essential points in the nature of the effort syndrome and the ways in which different forms of it arise. As it is brief the description is necessarily somewhat rigid. Clinically there are many cases which can properly be classified in the category of this disease, which do not have all the fully developed signs and symptoms. Many, for instance, are on the borderline between the states of pathetic and violent affectivity. A recent experience, such as induction into stirring military life, may so stimulate the "sympathetic" nervous system as to suppress only partially the existing pathetic emotional state. In such a resultant mixed state the heart action may be quite rapid and the arteries contracted only in comparison to their former condition, etc. (Pathetic affectivity must necessarily metamorphose into violent affectivity when an individual or a nation becomes a fighter.) The full emotional history of each case must be investigated in order to understand that case completely and it should be said that it is not necessary to use all the methods of so-called psychanalysis and also that the primary mental activity concerned is not by any means always of a sexual nature. I must repeat again the necessity of a good knowledge of both normal and pathological psychology in order to understand these cases and, in fact, the case of any human being whom we may be called upon to treat.

The effort syndrome appears in most patients about to undergo an operation and it constitutes one of the two chief forms of surgical shock.

The treatment of the effort syndrome is directed toward subduing and regulating the pathological activities. Psychotherapy must be used as indicated. In the primary group it is of paramount importance, for the patient's thoughts and emotions are immediately causative. In the secondary group psychotherapy is usually required, for, although the disturbing currents which are *causative* of the disease here do not originate in the *immediate* thinking of the patient, still such a patient is usually so much and so unduly concerned about his own condition and about everything else that psychotherapy is necessary. As a matter of fact, the secondary forms of the disease are usually, on account of the immediate thinking of the patient, complicated and aggravated by the primary form.

Bodily and mental rest is required in all cases, some requiring but little, others requiring very much. Essentially all patients can have some exercise, some being able, with more or less discomfort,

to attend to their usual occupation, others, especially the severe secondary ones, being able to take very slight exercise. However, it should be said that in many cases it is difficult for the patient really to rest, even while reclining, because the disturbing currents in the "sympathetic" nervous system so stimulate the organs of the body that rest is absolutely impossible unless proper medication is employed.

Medicinal treatment is of the utmost importance. The irritable activity of the mind, the brain, the sympathetic nervous system, and the bodily organs should be allayed by drugs. Use may be made of the following: gelsemium, bryony, cannabis, pulsatilla, lupulin, ailanthus, cimicifuga, sumbul, cramp bark, solanum, conium, cypripedium, sparteine, cactus, etc. Some cases require hypnotics. Occasional doses of vasodilators are needed in all cases. Iodides and thyroid extract are beneficial in some cases, especially those of the secondary group. Convallaria, digitalis, and strophanthus may be needed occasionally. Aconite is sometimes required. The doses of all medicines must be carefully regulated to suit the needs of the patient's condition. The chief thing that can be criticized about medication here is the fact that to produce the required effect on one organ the dose may have a greater effect than desired on another organ. However, medicinal treatment is most essential for proper recovery and in severe cases it is really life saving. It will, too, prevent some cases from being sent to the insane asylum under an erroneous diagnosis. These patients are far from being insane, if one knows what insanity is. They may be no more insane than the very best minds in any community. However, they are sick, they are very irritable, sometimes even irascible, and often irritably unreasonable.

Warm baths are good to supplement medicinal treatment.

The diet is regulated on general principles. In cases that have previously suffered from severe pathetic affectivity or prostration there may be some residual hyperchlorhydria to relieve.

The body should be kept sufficiently warm by ample clothing and house heating.

The general condition of the patient, particularly that of the whole nervous system, should be improved as far as possible.

The length of treatment in the mild cases of the primary group is sometimes fairly short, but in cases of the secondary group, especially those that have been prostrated, it is often very long and tedious, requiring many years. The prognosis, contrary to general belief, is excellent if proper treatment is intelligently employed.

125 Mary Street.

Volkmann's Disease in the Lower Extremity.—According to Souques, this ischemia paralysis has heretofore been regarded as almost peculiar to the upper limb. The case of the lower extremity which he submits is therefore nearly unique. The causation was identical, an overtight bandage. The greatest amount of retraction was seen in the calf muscles. The absence of all pain was a contributory factor in allowing the bandage to remain, while there were many symptoms referable to the sciatic nerve which were not associated in the mind with the tight bandage.—*La Presse Médicale.*

Medical and Surgical Lessons of the War.

POISON GASES IN WARFARE.

By Col. GEORGE G. NASMITH, C.M.G., Ph.D., D.Sc., D.P.H.,

TORONTO, ONTARIO.

SANITARY ADVISER AND OFFICER IN CHARGE WATER SUPPLY, FIRST CANADIAN CONTINGENT; OFFICER COMMANDING CANADIAN MOBILE LABORATORY, B. E. F. FRANCE.

In the early spring of 1915 vague rumors circulated along the British front in Flanders that the Germans intended to use a poison gas upon our soldiers. Little credence was attached to the rumors. About the middle of April a deserter from the German lines in the Ypres salient warned the British that the Germans intended to use a poison gas; but nobody believed him.

On April 22 the enemy, about 5 o'clock of a fine spring afternoon, projected his first gas cloud against our unprepared and unprotected troops, with results that were disastrous. The section against which the attack was launched was at the juncture of Canadian troops and French Colonial (Algerian) troops, a point which would, presumably, be weak. Within a few minutes a sector of some three miles, which had been occupied by the French Turcos, was devoid of infantry, which, terror stricken, streamed back through Brielen and Vlamertinge. Weak and partially stupefied many of them staggered into the Canadian Field Ambulances, with bloodshot eyes, severe coughs, dyspnea, and sometimes vomiting.

On this particular afternoon, in company with Captain (now Lieut.-Colonel) Rankin, I had gone into the salient to see what the country then occupied by our First Canadian Division looked like. Perhaps the account of our experiences on that occasion will be best gathered from that part of my diary quoted by Colonel Adami, C. A. M. S., in charge of Records Office, D. G. M. S., in his book, *The War Story of the C. A. M. C.*, 1914-1915. Colonel Adami writes:

"Lieut.-Colonel Nasmith was one of the first, if not the first, to advise Headquarters as to the nature of this gas—I quote from the diary of No. 5 Canadian Mobile Laboratory:

Merville, 22. 4.15. Worked till midday, and then left with Captain Rankin for Ypres . . . evidence of recent shell fire apparent. Draper's shop where I had dined the previous Saturday had been struck with a 17-inch shell and had disappeared. No troops about the city. Drove out to A. D. S. at Wieltje and was delighted to find Captain Scrimger, M. O. of the 10th there. After a chat, got out of the car, which could not go any further toward the trenches, and walked up the road for half a mile to see what it looked like. As we went along we saw to the left of the road, about four miles away, a long cloud of dense yellowish-green smoke rising and drifting in our direction. This cloud was apparently on a front of at least three miles, and started somewhere in the district where we knew the Canadians were and covered the line occupied by the French toward Bixschoote. We agreed that it was in all probability the poisonous gas which we had heard that the Germans talked of using. It resembled chlorine in general appearance, but occasionally we could see brownish fumes rolling over with it. The cloud looked at least thirty or forty feet high. A violent artillery duel began in the region occupied by the French and gradually spread along the section occupied by the Canadians. The gas reached us within half an hour, and we diagnosed it as largely chlorine, but with probably some bromine pres-

ent. Our eyes became bloodshot and ran water, and my throat became sore (subsequently my throat cleared up and a slight bronchitis appeared). There seemed to be another irritating gas present, but we agreed it was probably explosive fumes. . . .

Somewhere about six o'clock the Canadian artillery all around us began very rapid fire and we realized the situation was growing more serious. Red Cross French passed up the road from St. Julien and stopped to complain of the effect of the poison gases on their lungs. The first wounded Canadian came up in a cart from St. Julien, and a Canadian Highlander, black with powder and grease, said they had been left in a corner when the French retreated; that they had been surrounded by Germans. . . . French Algerian soldiers came running across the fields toward us. . . . We decided to move back. Wieltje was crowded with refugees and wounded. We picked up three and brought them along to Ypres.

All along the road we met Canadians coming up and saw them advancing across the fields in skirmishing order, in one case their captain walking ahead swinging a bamboo cane. . . . A bursting shrapnel bent in the metal body of the car while we were at Ypres. The shelling of Ypres was something terrific. . . . Roads blocked with refugees and transport . . . transport going up and refugees and French going down. Canadians drawn up all along the road. . . . Ypres on fire behind us.

23. 4.15. Wrote G. H. Q. direct, to save time, about chlorine and bromine gas which we had diagnosed at Ypres. Suggested the use of a pad soaked in hyposulphite of soda to protect the men, and suggested that the enemy probably already had one designed that might be obtained if search were made on the field.

23. 4.15. Was sent for by Sir Henry Rawlinson to tell what I knew about the gas used by the Germans at Ypres on the 22d. Told him all I knew. Drew a sketch for him of what I thought must have happened, and was surprised to find it was exactly right. Fourth Corps bulletin at night stated that prisoners said gas was contained in long cylinders; that men operating them used special rubber clothes and masks, and that the gas was projected forward through pipes—the gas was probably chlorine, the bulletin added. . . .

26. 4.15. Were visited by the A. D. M. S., 4th Corps, and several medical officers in the morning, all interested in the gas and its effects. In the afternoon General Sir Henry Rawlinson called with General Dallas and staff. The General again went into the question of the poison gas and methods for prevention and then asked to have the work of the laboratory explained.

28. 4.15. Sir William Herringham came in to ask about poisonous gases. He said, after listening to what we had to say, that Professor Baker had agreed exactly with our findings. . . .

1. 5.15. Took a letter of introduction round to laboratory where Professor Watson and his assistant, Mr. Jones, were working. . . . They had concluded that the gas used by the Germans was probably a mixture of chlorine and bromine, and had identified chlorine from the buttons of the coats of gassed soldiers. . . . Interested to know that my diagnosis of the gas was correct, and also that the respirator and solution advised were the ones being used.

Though he had broken the line by the use of the poison gas, the enemy was stopped by the heroic stand made by the Canadians and failed to win through to his objective—the Channel ports. By the use of the gas the Germans claimed to have killed 6,000 and taken as many more prisoners.

The first gas used was chlorine and was projected from cylinders as a cloud. These cylinders were brought into the front line, each one covered with a layer of moss containing potassium carbonate. They were then covered with sandbags and when about to be discharged were connected with lead pipe bent over the top of the parapet and held in position by sandbags. The poison gases which could be used in quantity great enough to produce a cloud were very few; in fact, chlorine was practically the only one manufactured in the huge quantities necessary for the purpose. The gas used had to be easily compressible, easily made on a large scale, of high density, very toxic, and preferably of low chemical activity. The choice was therefore practically limited to chlorine or its derivative, phosgene.

Presumably the enemy expected to obtain great military results from the use of the gas; had he foreseen what the effects would be he could have easily broken through, cut the British army from its base, and possibly settled the war then and there. As it was his effort left a battlefield such as has never been seen before or since except on the Russian and, possibly, the Italian fronts. But the enemy did not foresee, and therefore did not seem to be able to seize upon and exploit the favorable situation.

The success of a cloud gas attack depends largely on meterological conditions. The direction of the wind must lie between straight lines which make angles of 40° with the neighboring sections of front; the wind velocity must be within the limits of 4 and 12 miles an hour. It is better for the ground to slope away from the point of emission for then the heavy gas will roll slowly along, hugging the ground, and fall into the trenches, where its work was chiefly to be done.

It was quickly realized by chemists and physicists that there were three important factors in gas warfare. These were:

1. The use of new gases;
2. The element of surprise in attack;
3. The increase in concentration of the gases.

The first gas attacks were comparatively long, the one in May, 1915, lasting for nearly three hours. The enemy then got busy on the eastern front and used all his devices, including gas, against the Russians. Consequently he did not again discharge gas clouds on the Western front until December of 1915. During the interval the British Intelligence Department got news of some secret lectures given in Germany to a number of senior officers. These lectures indicated that phosgene was to be used and as this was a gas difficult to protect against there was a good deal of hurried experimental work to find an antidote. This was discovered in sodium phenate. When the attack came on December 19 the British had a helmet saturated with sodium phenate as the protective agent.

The December attack was made at night with a new gas and in very great concentration. It therefore fulfilled the possibilities of surprise, new material and increased concentration. This attack lasted thirty minutes and other subsequent attacks were even shorter, lasting only ten or fifteen minutes, which meant one cylinder for every two feet of front. It was discovered that the times were best when there were downward currents of air, such as between dusk and dark or just before sunrise.

The discharge of a second gas cloud some time after the first one was another method employed. The men, thinking the attack was over, would remove their masks and ten minutes to half an hour later would be caught by the second discharge over the same front. Near Hulluch, in 1916, our men

were thus caught badly by a second gas cloud much stronger than the first.

Another device used was to alternate the gas clouds with smoke clouds, so that it would be difficult to tell where one attack ended and another began. Efforts were also made to prevent the hissing sound made by the escaping gas by reducing the rate of discharge, but this was offset by the reduction in the concentration of the gas cloud. It was obviously important to send over the gas in as great strength as possible so that the unwary or unprepared soldier or the man with a defective helmet should not escape. The writer knew of one officer who got a single breath of phosgene gas before he could get his gas helmet adjusted. He carried on and subsequently walked back to his battalion headquarters, where he dropped, was brought into the hospital across from our laboratory, and died within 24 hours of the time he had been gassed.

The preventive measures employed by the British against cloud gas were so efficacious that after the 1st of August, 1916, no further attacks of this sort were made against them. Three attacks were subsequently made against the French and also against the Russians and Italians.

Before the last gas attack on the British the casualties from this source had been reduced to a minimum, as shown by the fact that the percentage of deaths was high. In this last attack our men were caught during a relief when carrying full kit and when twice as many men as usual were in the trenches.

The success of a cloud gas attack depended on thorough preparation beforehand. The country, the layout of the trenches and the direction and velocity of the wind had to be known with certainty. A wind of more than 12 miles an hour dispersed the gas cloud very rapidly. The time occupied by a gas attack under favorable conditions was too short to permit of much diffusion of the gas out of the original mixture.

The gas attack had to be planned very carefully, for where the trench line was irregular the gas might flow into a portion of one's own trenches. The limits of safety in wind direction were thus determined by the direction of the lines of the trenches. The Germans made the mistake of believing that hilly or wooded country would not do. The French, however, made a successful gas attack in the hilly and wooded country of the Vosges, as admitted in a captured German report. Where the country was flat like that about Ypres, and the wind direction was right, there was little difficulty in making an attack, especially when the enemy did not know anything about it. The element of surprise was important.

German gas attacks were made by two regiments of pioneers, with highly technical officers, including engineers, meterologists and chemists. The element of surprise was greatly lessened when we began to know what to look for and to recognize the sounds incident to the preparation of a gas attack.

Poison gases are divided into cloud gases and shell gases. After August 1 on the British front the cloud gas was practically superseded by gases contained in shells.

Shell Gases.—In trench warfare the Germans developed hand grenades of glass and metal which they used when on raids for clearing dugouts and killing sappers. The grenades were filled with such liquid chemicals as bromine (meaning stench) and chlorsulphonic acid, which fumed violently on exposure to the air, giving off suffocating and poisonous vapors.

The use of the gas shell was elaborated by the Germans soon after they had developed the gas cloud. This afforded the opportunity to employ a variety of substances unsuitable for gas cloud, although chlorine and phosgene were also used in shells. These two substances were liquid under pressure, as has been noted, and only a small powder charge was required to crack the shell when it reached its destination. The liquid immediately vaporized and produced a local cloud. The difference in sound as they burst made their detection easy.

The gas shell was extensively developed. Heavy corrosive liquids and even solids were charged into the shell provided with a high explosive, such as TNT, which on explosion by means of a suitable fuse converted the liquid into a mist, or the solid was so finely pulverized as to become a dust cloud. These particles of mist or dust were of such small size that it was thought they would pass through the pores of the protecting hood or mask then in use. They were also less reactive with the chemicals used in the first filters. Furthermore, the mist would attach itself to the clothing, or cling to the ground, and slowly evolve poisonous or irritating vapors long after the gas shell bombardment had ceased. Men were often thus poisoned by these delayed vapors some time after the bombardment.

All the substances used were not necessarily of a poisonous nature, unless in great concentration. One class of these substances, known as "tear shells" or "lachrymators," were among the first used by the Germans. They used this "T-Stoff" (xylyl and benzyl bromides) in 1915. One part of these in a million of air by volume causes the eyes so to water as seriously to interfere with vision. Temporary blindness usually resulted from higher concentrations, which, when very great, produced nausea and vomiting.

Several other "stoffs" were used: for example, "B-Stoff" (brominated methylethyl ketone), "Green T-Stoff" (a mixture of xylyl bromide and bromacetone), each having particular tactical values.

When the enemy observed that the Allies were learning the game and their gas attacks were becoming less and less effective on account of the defensive means (masks) employed, they brought into play (1917) a "blue cross" (so marked) or "sneezing shell." This shell was filled with a solid (diphenylchlorarsine), mixed with a high explosive. The explosion was very similar to that of shrapnel or high explosive shell. The fine powder not only affected the respiratory organs, but caused sneezing, involving such deep abdominal muscles as to provoke vomiting. The evident purpose was to prevent the soldier from adjusting his mask or force him to remove it and be poisoned by the sneezing stuff (in great concentration) or by other gases which were discharged in the same area simultaneously.

"Tear" shells containing almost pure xylyl bro-

mide or benzyl bromide, were made by brominating the higher fractions of coal-tar distillates.

If the bromination was not done carefully too much dibromide, an inactive solid, was produced. Some of the shells contained as much as twenty per cent. dibromide, enough to make the liquid pasty and worthless. The shells used contained a lead lining, and had a partition across the shoulder, above which came the T. N. T. and the fuse. These shells had little effect on the British, but one attack on the French, accompanied by a very heavy bombardment with tear shells, affected the eyes of the men and many were even anesthetized by the gas and taken prisoners.

The first important experience of the British was an attack near Vermelles. The Germans put down a heavy barrage of these shells and made an infantry attack. The concentration was great; the gas went through the helmets and the men even vomited inside their helmets. But a gas barrage is difficult and in the instance cited certain roads were not cut off sufficiently so that reinforcements got up. This attack, however, opened our eyes to the fact that, as in the case of gas clouds, concentration could be developed so as to produce the required effect under any circumstances.

When the Germans began using highly poisonous shells on the Somme in 1916, they did not do it well, although enormous numbers of shells were used. The substance used was trichloromethyl-chloroformate, but not in great strength. It had no decided reaction on the eyes and the men were often caught unprepared.

The quantity of gas that could be sent over in shells was small. The average weight in a shell was not more than six pounds, whereas the German gas cylinders contained forty pounds of gas. To put over the same amount of gas as in a gas cloud, say in five minutes per thousand yards of front, would require a prohibitive number of guns and shells. It was necessary to put the shells on definite targets, and this, fortunately, the Germans did not realize at the Somme, although they found it out subsequently.

The use of gas out of a projectile had a number of advantages over its use in a gas cloud. It was not so dependent on the wind. Again, the gunners had their ordinary routine of shelling, and there was no such elaborate and unwelcome organization to put into the front trenches as was necessary in preparing for the gas cloud. The targets, too, were picked with all the accuracy of artillery fire and finally the gas shells succeeded with targets that were not accessible to high explosives or to gas clouds. For example, in a gun pit with a certain amount of overhead cover for the men the men were safe from splinters and only a direct hit could put the gun out of action. But the gas entered where the shell would not and was certain to affect some of the men inside the emplacement. The crew of the gun had to go on firing with gas masks on, and with reduced numbers, the number of shots lessened or the gun even entirely silenced.

Where a position was located on a hillside with dugouts at the back, just beyond the crest, or with a sunken road behind the slope, almost complete protection was afforded the men in the dugouts from ordinary shell fire; but not from gas. The French failed to take one such position three times with a high explosive bombardment, but succeeded after using gas shells, for the gas flowed into the dugouts like so much water and accomplished its purpose.

Among the effective materials used by the Germans for gas shells were mono- and trichloromethyl-chloroformate. Prussic acid never appeared; the Germans rate it lower than phosgene in toxity, and the reports concerning it were obviously meant merely to produce fear and distract the provisions for protection. Lachrymator shells were used as a source of annoyance. Mere annoyance, however, may be an effective method of neutralizing infantry. For instance, where large amounts of supplies and ammunition were being brought up to the front, there always were cross-roads where there was confusion and interference of traffic. A few gas shells placed there made every man put on his mask, and if it was a dark night and the roads were muddy the resulting confusion can be only faintly imagined. It was thus possible to neutralize a part of the infantry by cutting down their supplies and ammunition.

The use of a gas shell to force a man to put on his mask was practically neutralization. If at the same time you could hurt him, so much the better. Hence the change in gas-shell tactics, which consisted in replacing the purely lachrymatory substance by one that was also poisonous.

As already noted the use of gas shells in their development gave wide range of employment of toxic substances in this chemical game of hide-and-seek. Poisonous liquids which would evolve a vapor from 3 to 6.6 times as heavy as the air were employed. The liquids, or their mists, coming into contact with the skin, as the hands or the neck, would produce blisters, and mean sores. Coming into contact with rubber, of which parts of the masks were composed, some of them rendered the rubber brittle and the mask became useless. Absorbed by the clothing, they penetrated to the skin, or continued evolving poisonous fumes for a day or more. These liquids also wet the soil with which they came into contact. A soldier leaning against a sand bag or sitting on the ground so wetted could thus unconsciously become affected.

One of these substances was "mustard gas." It is not, in fact, a gas at all, nor is it the real mustard oil, but a liquid (B B dichlorodiethyl sulphide), which gives off a vapor over five times as heavy as the air, with a faint, garlic-like odor.

It came into use at Ypres and it was largely used again at Nieuport and Armentieres. A heavy bombardment of mustard-gas shells of all calibers was put down on these towns, as many as 50,000 shells being fired in one night. The effects of mustard gas are those of a "super-lachrymator." It has a distinctive smell, rather like garlic than mustard. It has no immediate effect on the eyes beyond a slight irritation. After several hours the eyes begin to swell and inflame, causing intense pain, the nose discharges freely, and severe coughing and even vomiting ensue. The respirators, of course, did not protect against blistering. The cases that went to the hospitals, however, were generally eye or lung cases, and blistering alone took back very few men. Many casualties were caused by the habit that some of the men had fallen into of letting the

upper part of the mask hang down so as not to interfere with seeing. The Germans scored heavily in the use of this gas at first. It was another example of the element of surprise in using a new substance that produced new and unusual symptoms in the victims.

Each of the substances mentioned and others used by the Hun, which have not been referred to, has its own characteristic physiological action that was taken advantage of in tactical application, involving primarily surprise. All that is known to us is what has been learned through prodigious researches of the chemists of the Allies and from captured documents. The following compounds were used by the Germans in gas clouds or in shells:

1. Allyl-iso-thiocyanate (allyl mustard oil), C_3H_5NCS (shell).
2. Benzyl bromide, $C_6H_5CH_2Br$ (shell).
3. Bromo-acetone, $CH_2Br \cdot CO \cdot CH_3$ (hand grenades).
4. Bromated methyl-ethyl-ketone (bromo-ketone), $CH_2Br \cdot CO \cdot C_2H_5$ or $CH_3 \cdot CO \cdot CHBr \cdot CH_3$ (shell). Dibromo-ketone, $CH_2CO \cdot CHBr \cdot CH_2Br$ (shell).
5. Bromine Br_2 (hand grenades).
6. Chloro-acetone, $CH_2Cl \cdot CO \cdot CH_3$ (hand grenades).
7. Chlorine, Cl_2 (Cloud).
8. Chloromethyl-chloroformate (palite), $ClCOOCH_2Cl$ (shell).
9. Nitro-trichloro-methane (chloropicrin or nitro-chloroform), CCl_3NO_2 (shell).
10. Chlorosulfonic acid, $SO_3H \cdot Cl$ (hand grenades and "smoke pots")
11. Dichloro-diethylsulfide (mustard gas), (CH_2CLCH_2) S (shell).
12. Dimethyl sulfate, $(CH_3)_2SO_4$ (hand grenades).
13. Diphenyl-chloro-arsine, $(C_6H_5)_2ASCl$ (shell).
14. Dichloromethyl ether, (CH_2Cl) O (shell).
15. Methyl-chlorosulfonate, CH_3ClSO_3 (hand grenades).
16. Phenyl-carbylamine chloride, $C_6H_5NCCl_2$ (shell).
17. Phosgene (carbonyl chloride), $COCl_2$ (cloud and shell.
18. Sulfur trioxide, SO_3 (hand grenades and shell.)
19. Trichloromethyl-chloroformate (diphosgene, superpalite), $ClCOOCCl_3$ (shell).
20. Xylyl bromide (tolyl bromide), $CH_3C_6H_4CH_2Br$ (shell).

Gas Masks.—Within a week of the first gas attack at Ypres on April 22, 1915, a million gas masks were made by the women of England and sent out to the army. Most of them were made wrong and were perfectly useless, but a pad of cotton waste held between two layers of cheese cloth, soaked in hyposulphite of soda and tied over the mouth and nose was speedily adopted and issued as the first defensive measure. It was quite efficacious and doubtless saved many lives.

Then came the helmet made of a flannel bag soaked in thiosulfate and carbonate, with a mica window in it. A modified form of this device with different chemicals was used in the British army to the last as a reserve protection. It was put over the head and tucked into the jacket, and was foolproof as long as well tucked down. This stood up very well against chlorine.

The protection that had been devised against phosgene proved effective at the time, but provision was made to meet increased concentration of phosgene. There never was any direct evidence that phosgene was being used, as no samples were actually obtained from the cloud, but cylinders of phosgene were captured later. For obtaining gas samples glass vacuum tubes, about 10 by 30 cm., with a tip that could be broken off and then closed by a plasticine-lined glass cap, were distributed, but the only one that came back was an unopened tube found in a hedge and marked by the finder: "Dangerous; may contain cholera germs." During a gas attack everybody kept quiet and conditions were not conducive to the taking of gas samples.

There was a long search for materials that would absorb phosgene, as few substances react readily with it. The successful suggestion came from Russia. The substance finally used very extensively by all was hexamethylenetetramine (urotropine), $(CH_2)_6N_4$, which reacts very rapidly with phosgene. Used in conjunction with sodium phenate, it will protect against phosgene at a concentration of 1:1000 for a considerable period. An excess of sodium hydroxide was used with the sodium phenate, and a valve was provided in the helmet for the escape of exhaled air. The valve was originally devised so that the hydroxide would not be too rapidly carbonated, but it was found in addition that there was a great difference in ease of breathing and comfort when a valve was placed in the mask.

The concentrations of gas usually met with were really very low. As has been said, a high concentration for a gas cloud was 1 part in 1,000, whereas concentrations of two or three per cent. could be met by respirators depending on chemical reactivity. One such respirator was a box of chemicals connected by a flexible tube with a face-piece fitting around the contours of the face, and provided with a mouthpiece and nosepiece.

Active absorbent charcoal was one of the main defenses, and was another suggestion that we owe to the Russians. Wood charcoal was used in one of their devices and was effective, but most of the Russian soldiers had no protection at all.

We wanted to protect against chlorine, acids, and acid-forming gases, phosgene, etc., and at one time were fearful of meeting large quantities of hydrocyanic (prussic) acid (HCN). At one period every prisoner taken talked about the use of prussic acid, saying that the Kaiser had decided to end the war and had given permission to use prussic acid. Protection was evidently needed against it. The three things that then seemed most important were: (1) chlorine and phosgene; (2) prussic acid; (3) lachrymators. Charcoal and alkaline permanganate would protect against nearly everything used, even up to concentrations of 10 per cent. for short periods.

The German apparatus, developed about the same time, was of a different pattern. It consisted of a small drum, attached directely to the front of the face-piece, and weighed less than the British respirator, but had to be changed more frequently. It had no mouthpiece. The chemicals were in three layers: first, an inside layer of pumice with hexamethylenetetramine; in the middle, a layer of charcoal (sometimes blood charcoal); and outside, baked earth soaked in potassium carbonate solution and coated with fine powdered charcoal.

It is a well known fact that charcoal absorbs different gases to different degrees. The absorptive value depends upon the character of the carbon and its method of production. Thus the charcoal from cocoanut shells, peach pits, and ivory nut is very effective and such material, granulated to

definite size and mixed with granules of certain chemicals, reacts with and absorbs objectionable gases drawn through them. The mixture of charcoal and chemicals, in proportion carefully determined beforehand, is placed in the filter canister to which the flexible intake tube referred to is attached. The masks are provided with non-shattering goggles constructed so as not to be dimmed by condensing moisture and yet allow of clear vision for the soldier in using his rifle or looking after his gun if he happened to be an artilleryman.

The efficiency of any filter depends upon the fineness of the pores of the filtering medium. Chemical action, which is essential for the destruction of the toxic bodies, depends upon intimacy of contact of the agents involved. The smaller the pores, all other things being equal, the purer is the air breathed. These interstices, however, may be so small as to place too heavy a burden upon the breathing apparatus of the soldier who gets insufficient air, especially under the active physical exertion of battle. That means the production of incomplete oxidation products in the body, which spell abnormal fatigue.

In the prosecution of the researches, in both offensive and defensive gas warfare, it was necessary to make many animal experiments. These had to do not only with human beings, but were concerned as well with the conservation of our horses, mules, donkeys, carrier pigeons, and dogs. It was necessary to protect horses and mules only from the toxic agents; dogs and carrier pigeons also had to be protected from tear gases. All were provided for with special masks.

The Germans did not alter their type of respirator for some time, and it was not equal in efficiency to the British or American respirator. The German respirator, even in its latest form, broke down at a concentration of 0.3 per cent. of certain substances. The German design gave more weight to military exigency, as against perfect protection, than did the British. Another thing that weighed against changes in design was the fact that the German, already handicapped by the lack of certain materials, had to manufacture 40,000,000 respirators a year in order to supply his Austrian, Bulgarian, and Turkish allies, as well as his own army.

In the American and British armies the respirator *had always to be carried with the equipment when within twelve miles of the front.* Between 12 and 5 miles a man could remove the respirator box in order to sleep, but within 5 miles he had to wear it constantly. Within 2 miles it was worn constantly in the "alert" position (slung and tied in front). When the alarm was given he had to get the respirator on within six seconds. The American respirator was identical with the British. The French had a fabric mask made in several layers, the inner provided with a nickel salt to stop HCN, then a layer with hexamethylenetetramine; it had no valve and was hot to wear. The French also used a box respirator, consisting of a metal box slung on the back, with a tube connecting to the face-mask; the latter was of good para rubber and was provided with a valve. One disadvantage of this form was the danger of tearing the single rubber sheet. The German mask latterly contained no rubber except one washer; the elastics consisted of springs inside a fabric, and the mask itself was of leather. It hardened and cracked after being wet, and was too dependent upon being well fitted to the face when made.

The heinous action of the Germans in using poison gases in contravention to all agreements naturally found the Allies unprepared for such criminal procedure. Reference has already been made to the makeshift steps taken at first to meet the emergency. Once, however, it was recognized that the Germans meant to pursue such practices with utter abandon and apparently without restriction, the chemists of the Allies set about formulating the fundamental principles involved in the protection of troops against enemy gas attacks and the various procurement bureaux sought to provide the necessary equipment. This resolved itself, first, in nullification, or purification, of the contaminated air the soldier was to breathe; and second, into elimination of accumulated gas in trenches, dugouts, or topographic depressions in which the heavy poisonous air might accumulate.

In regard to the latter it was highly desirable to prevent the ingress of the gas. Such was quite out of the question in open trenches and valleys, but well-constructed dugouts could be and were battened down with heavy blankets, which were kept wet, usually with solutions of chemicals. The Germans sprinkled chloride of lime, or sprayed a water solution of that chemical, in trenches contaminated with "mustard gas." This phase of the problem resolved itself into a matter of ventilation. The contaminated atmosphere was removed by creating air currents by means of fires, or better by fanning or shoveling the air out of the trenches with large canvas fans or paddles—a suggestion of Lady Ayrton, the prominent physicist.

The efficiency of the ventilation is closely associated with the question of concentration of the contaminating gas and the specific physiological action of the toxic agent employed. All poisons are harmless when in extreme dilution. The first dose under considerable dilution may exert decided physiological action. The familiar events incident to the first cigar illustrate this. An individual becomes in time more or less immune, as we know from the number of cigars smoked per day by many men. So the soldier in time may become more or less immune to weak poisons and is not disturbed by breathing them. We have thousands of instances of this daily among workmen in chemical factories. If we accumulate all the nicotine, tarry matters, and other products of combustion or solution from the ten cigars an inveterate smoker burns in a day and give it to him in one dose, down he goes. So it is with gas in warfare.

The effects of poison gases on human beings.—In a paper on the effects of the inhalation of chlorine gas Schäfer in 1915, showed the results of experimental work on dogs, cats, and rabbits which had been allowed to inhale chlorine gas of different concentrations. The animals were previously anesthetized. His conclusions were that the effects of chlorine gas were local and that any chlorine absorbed by the blood stream would be immediately neutralized there. When air containing one per cent. of chlorine was breathed the ani-

mal blood pressure after several minutes fell rapidly and respiration ceased. Autopsy showed the lungs to be congested.

Schäfer thought that the fatal result was due to obstruction of the pulmonary vessels, making it impossible for the blood to pass freely to the left auricle and ventricle. He showed that contrary to common opinion chlorine did not cause constriction of the bronchioles.

Confirmation of his conclusion he thought was obtained as a result of the miscroscopic examination of the lungs of gassed animals. In all cases the pulmonary capillaries were gorged with blood. There was edema in the interstitial tissue and the alveoli contained blood. Otherwise the lungs were normal. To show that the secretion of mucus did not play an important part, in some cases he inoculated an animal with atropine, previous to the introduction of the chlorine, with the same results. The other organs of the body were comparatively normal, except that the vena cava was filled with blood.

A few experiments with bromine gas showed that it had less effect on the respiratory organs than chlorine.

Prof. Leonard Hill classified poison gases into those (1) that klll by cutting off the supply of oxygen, *e.g.* hydrogen and nitrogen dilute the atmospheric oxygen below the viable amount and CO combines with the hemoglobin and thus prevents the carriage of oxygen to the tissues. (2) Cyanogen, hydrogen disulphide, and HCN kill by paralyzing the respiratory centre. (3) Those that acutely irritate the respiratory passages, causing an exudation of lymph which drowns the subject. It is the last set of gases which the Germans used because they put a man out of action when breathed for a shorter time and in greater dilution than any other poison gas and because they are heavier than air.

The effect of a 1:10,000 dilution of chlorine is such that those who can escape will not breathe it. The eyes and the mucous membrane of the respiratory tract are intensely irritated, and a watery exudation takes place—the inevitable effort which the living tissues make to dilute so irritant a poison. The epithelial lining is damaged by the poison, both that of the mucous membrane and the capillary wall. In the earliest stages the salivary glands in the mouth and the mucous glands in the air tubes are stimulated to secrete just as the tear glands flood the eyes.

It is this pouring out of fluid in a vain effort to dilute the poison which causes the asphyxial symptoms of chlorine poisoning and finally drowns the man. Chlorine is much more toxic when it comes in contact with a moist living membrane in a gaseous state than when in watery solution. Broadbent, talking about nephritis following chlorine poisoning says: "It looks as if in some cases the chlorine or bromine damages the lung epithelium so severely that it does not allow absorption into the general circulation, while in others it passes through the lungs without affecting them permanently, but then sets up an acute nephritis." Hill denies this and says in every case chlorine expends its fury on the lungs. He says nephritis is due to the prolonged dyspnoea and the struggles for breath.

Hill disputes Schäfer's conclusion that death is the result of stasis in the pulmonary system. He says that Schäfer used chlorine gas in high concentrations, *e.g.* ½ % and over, while on the field the concentration is much lower than this. Bromine in a concentration of 1:1000 kills the mucous membrane, which may be stripped off and suffocate the animal. Chlorine causes a greater exudation of fluid than bromine. Chlorine (1:1000) in a cat causes exudation which fills up the trachea and if it is squeezed out great relief results.

He made an experiment as follows: It was arranged that an animal was artificially respirated with pure air into one lung and chlorinated air into the other. In the latter lung they saw a gradual production of edema, congestion, and lessened expansion, and failure of circulation. On respirating the other lung with pure air the circulation immediately and completely recovered. They now squeezed fluid out of the first lung, and saw that circulation may continue. It is well known that a large part of the pulmonary circulation can be ligatured and yet an adequate circulation be maintained through the remainder. The experiments show how artificial respiration could keep alive the poisoned animal.

Symptoms and Lesions of Lungs in Poisoned Animals.—Animals exposed to chlorine first show profuse watering of the eyes and salivation, respiration becomes quickened, and then as the edema of the lungs and the exudation into the air tubes increases respiration becomes slower and laboured. The mouth gapes and a frothy secretion exudes from the mouth and nose. The whole effort of the animal is given up to breathing. Finally it falls over exhausted, the breathing becomes rarer and shallower, and the animal dies. Examination of the lungs in the first twenty-four hours shows an intense congestion and the air tubes contain a frothy exudation. Animals which die late show more or less intensive patches of red hepatization. (This description corresponds very closely with that of the autopsies on soldiers.)

Hill says that there is no doubt the first effect of a concentration such as 1:1000 is to cause a contraction of the bronchial muscles, and diminish the expansion of the lungs. He thinks that Schäfer in using concentrations of ½ per cent. killed the lining membrane of the tubes including the muscles.

From his experiments Hill thought that artificial respiration would be very useful in order to get rid of the secretion. Also that forcing air into a man's lungs even at the risk of producing emphysema might keep a man alive. He also suggested using oxygen through a mask a suggestion that was adopted with good results. Experiments on animals showed that compressed air relieved dyspnea to the same extent as oxygen does, and he suggested the use of compressed air locks in which to place the patient. Atropine was found to be of no service. Stramonium vapor relaxes the bronchial muscles, and might afford slight relief.

Mott found that the brains of men dying from shell-shock and gas poisoning were similar to those of men poisoned with nickel carbonyl or carbon monoxide where multiple punctate hemorrhages occurred throughout the white matter of the brain.

Miller found that in cases of gas poisoning,

where symptoms persisted, there was an absolute and relative increase in the number of leucocytes. He concluded that where the percentage of lymphocytes approached that of the polymorphonuclears the patient was still suffering from the effects of the gas—providing other complications were eliminated. The small lymphocyte he found to be the cell which was increased and concluded that chronic inflamatory change in the respiratory and gastric mucous membranes was at least a factor.

R. de La Riviere and J. Leclecq observed 112 cases of gas poisoning (chlorine and bromine) within a few hours after gassing. Pulmonary symptoms were usually most prominent. These patients showed all the evidences of dyspnea and asphyxiation. There was spasmodic cough, and at the time of the greatest violence of coughing the patient always pressed the sides of the chest between his hands. Thre was abundant expectoration, frothy and reddish, sometimes blood stained. Speech was painful and interrupted. On examination the lungs showed an inflamatory condition extending to the finest bronchial ramifications. Expectoration consisted partly of a gummy glutinous portion that adhered to the vessel, and partly of a portion frothy and a little purulent. Vascular tension was increased. Temperature was slightly elevated 98°-100°F., in some cases to 103°F. In the majority of cases the alimentary tract showed a furred condition with anorexia and a sensation of discomfort or of burning along the course of the esophagus, and over the gastric region. Some of the patients showed absolute intolerance for food for many days, and suffered from recurrent attacks of vomiting of alimentary debris and of biliary matter, and in some cases a little blood. Some of the affected soldiers suffered from diarrhea for a number of days. In a certain number of cases the liver was enlarged and painful. In more than half the cases pains were complained of in the lumbar regions, and the majority passed urine of diminished quantity, concentrated, and of a high color. Eighty per cent of the patients recovered very rapidly. In some cases bronchopneumonia, pneumonia, and pulmonary gangrene were complications. Two patients showed symptoms of hemolytic icterus, and a large number suffered from permanent albuminuria.

An examination of the sputa showed at the outset fragments produced in desquamation together with some pus cells, and afterwards showed the results of congestion, and in some cases the actual necrosis of pulmonary tissues. At first the bacterial flora was normal, but in a certain number of cases it showed the presence of *Bacillus perfringens* and *B. serpens,* which are usually associated with pulmonary gangrene.

Black, Glenny, and McNee, who worked in one of the casualty clearing stations in Bailleul, had probably the best opportunity for careful study of cases of chlorine and phosgene gas poisoning. They were located close to the scene of several of the enemy gas attacks in and near the Ypres salient and as some of these occurred before preventive measures came into force they had unrivalled opportunities for observing the effects of the gas.

One night we drove from Merville to Bailleul to call on McNee and the officers of that hospital and found that several hundred gassed cases had come in to their wards that afternoon and were even then dying like flies.

The paper by this trio, for the reasons given, may probably be considered the most exhaustive and reliable report on the effects of cloud gases. Many of the observations here recorded were confirmed by Captain Ellis and Major Rankin who were associated with me in laboratory work but who studied many of the gassed cases and performed a number of autopsies.

The paper gives the symptoms and treatment of 685 cases and the pathology of ten cases which came to autopsy. All the cases seen were in the acute stages, but only remained under observation for a few days. It was observed that some cases showed much worse symptoms than others, although the exposure was the same. Older men were almost always severe cases. Clinically cases could be divided into two classes (*a*) those in imminent danger of death from asphyxiation (*b*) those not in immediate danger.

On admission the typical case was cold, with a subnormal temperature, conscious but restless, a pulse slow and full (except in collapsed cases) the face was cyanosed especially the lips and ears, and the expression was strained and anxious. Some of the patients sat propped up with head thrown back gasping for breath while others lay on the side with their heads over the edge of the stretcher in an attempt to aid expectoration. Respirations were jerky and hurried, often as high as forty per minute, and there was a choking cough with a varied amount of frothy expectoration. With each inspiration the chest was expanded to its fullest, all the auxiliary muscles being brought into play as in asthma. Moist rales were heard over the chest, and resonance was diminished.

Those patients who lived passed through three stages. (1) Asphyxial (2) quiescent (3) bronchitic. Most of the cases on admission were of the first type, and required energetic treatment. This stage lasted usually 36 hours and if they came through this safely they usually recovered. At the end of this time they fell asleep and woke feeling much easier. The later state lasted for about half a day. Then symptoms of bronchitis began to show. In most cases this was not severe, but in those cases where the first stage was very acute, bronchitis was usually severe. The symptoms of these acute cases were as follows: The frothy secretion gave way to a greenish muco-purulent expectoration, patient became delirious, temperature rose from sub-normal to 104°F., pulse became small, and its rate increased to perhaps 160. Respirations were more shallow and increased to 70 per minute.

Treatment.—The aim of the treatment was to diminish and expel the secretion, and to support the failing heart. The general treatment was fresh air and warmth. Various emetics were tried and that which proved to be most successful was to give the patient salt and water in ten ounce doses, followed by draughts of lukewarm water, and induce vomiting by tickling the throat. The patients brought up large quantities of yellowish frothy fluid, and relief was pronounced. In some few moribund cases artificial respiration was also used

to aid the emetic. Expectorants were then given, and ammonium carbonate in 15 gr. doses every three hours was found to be the most beneficial. Atropine was tried to diminish secretion, with but little results. To support the heart venesection was tried with no good results. Pituitary extract administered when pulse was very weak was helpful. Oxygen was given freely by inhalation and temporarily reduced the cyanosis. Compound tincture of benzoin (Friar's balsam) was given in some inhalations with some relief. Opium was of use in cases where mental strain was a more marked symptom than the pulmonary condition. The routine treatment evolved was as follows: (1) Abundant supply of air and warmth. (2) Emetic of salt and water if the patient was very cyanosed, and had not already vomited. (3) Ammonium carbonate, gr. xv., and wine of ipecac, ℥ xv. every 3 hours. (4) Tincture of opium, v., x., or xv. in restless cases. (6) Pituitary extract and brandy when the heart shows signs of failing.

Autopsy findings.—All cases were those dying within 5 days, and the most important changes were in the heart, lungs and stomach. The larynx and trachea were congested, and the bronchi were filled with a thin, light yellow, frothy, secretion. The smaller bronchi could not be traced owing to the intense congestion and edema which affected the lungs as a whole. The lungs were large and much heavier than normal. The pleural surfaces were mapped out into areas of light grey and dark greyish brown. There were small subpleural hemorrhages. The light grey areas were patches of emphysema and were most common on the edges of the lungs and the diaphragmatic surfaces. These areas were not more than half an inch deep. Areas of congestion alternated with areas of emphysema. The heart was distended, but especially the right heart. The stomach in all cases showed a condition of marked catarrh with a thick yellowish mucus and submucous hemorrhages. The other organs and also the brain showed congestion.

On microscopic examination in the areas of congestion in the lungs the capillaries were engorged and many of the alveoli were filled with an albuminous secretion. The emphysematous portions showed alveoli very greatly distended and many broken down. Here, of course, the capillaries were not congested, and all the bronchioles were empty

In a paper on the treatment of chlorine gas poisoning, Hebblethwaite advocated venesection in cyanotic cases. In the cardiac-failure type of case the patient was pallid, collapsed and required no bleeding. They were suffering from cardiac failure due to a cause other than that of overstrain caused by increased resistance through the pulmonary system. Cardiac stimulants were required, and venesection had no marked results. The congestion found was secondary to the cardiac incompetence. The cyanotic type were in the majority. Patient was deeply cyanosed, very dyspneic, but with a strong pulse, and the immediate trouble was due to the heart becoming increasingly weaker from overstrain in working against an increased pressure through the pulmonary system due to the inflammatory condition of the alveoli.

Theoretically the results of venesection are as follows: (1) Resistance to the heart is lowered in ratio to the amount of blood withdrawn. (2) The resulting abstraction of blood from the lungs leads to a lessened resistance through the pulmonary system.

Practically the results were: (1) Relief of cyanosis; (2) relief of congestion of the lungs, enabling the patient to breathe more easily; (3) relief to the acute headache; (4) promotion of sleep. Time is very important. Early action is necessary. The longer the heart has to work against an increased peripheral resistance the weaker it becomes. *Method:* From a vein of the arm fifteen to twenty-five ounces was taken in fifteen to twenty minutes. The results in all were practically the same, as above. The writer believes that depletion of blood gave rest, which was sorely needed. Venesection was not found to be of any value in the experience of Black, Glenny and McNee just narrated. Mandel and Gibson stated that there was an interval of four to sixteen hours of freedom from distress between the time of gassing with mustard gas and the onset of symptoms. The latter are conjunctivitis, laryngitis, bronchitis, and skin burns, all due to the excoriating effect of the gas. Complications are early pulmonary edema, and relatively late bronchopneumonia. Dry clothing and sleeping quarters may prevent the development of symptoms after slight exposure, and possibly may lessen the severity in those more extensively gassed.

Custom says that the lachrymogenous shells usually did not produce serious effects, and the soldier generally recovered in a few hours. The symptoms he described are the same as given. He classified the cases according to the evolution of the symptoms into four types: (1) that with sudden onset; (2) with a retarded onset; (3) a type of short duration, and (4) a prolonged type. As to complications we have primary or those arising during the evolution of acute accidents, the late or secondary following, and lastly the distant complications. Among the primary are pulmonary and subcutaneous emphysema as a result of the coughing. The secondary involve the lungs and the stomach, bronchopneumonia, pneumonia and foetid bronchitis. The distant complications so far met with are gastric disturbances.

Mustard Gas.—The *American Journal of the Medical Sciences* says: The effects of lachrymatory gas were all over quickly, and no harmful results remained.

Mustard gas produced inflammation of the eyes in at least eighty per cent. of the cases. This gas works best in the presence of moisture and, therefore, it affects mostly the mucous membranes and the moist surfaces of the skin, the axillary folds, and the genitals. The direct effects of the gas are delayed for three to eight hours. The soldier vomits, his eyes begin to burn and water, and the lids often swell. The respiratory passages are very irritable, and severe attacks of coughing come on. The skin lesions are seen later and vary in severity from a mild erythema to a marked development of bullæ on the affected parts. Many cases are very mild. The mortality is about two per cent. and the commonest cause of death is bronchopneumonia. The eye lesions are in the nature of a chemical burn, and the skin of the lids, the conjunctivæ, and the

cornea are affected. The lids are reddened, swollen, and often show bullæ, and are kept tightly closed. Irritation and photophobia are intense, and the conjunctivæ are injected according to the severity of the case. In the more severe cases there is a very marked white edema and chemosis. A secondary infection following upon gassing is very common. In the more severe cases the cornea may be involved, varying from a slight roughening to a well-defined opacity.

Nearly one-third of the cases may be discharged to duty in a week, and one-third more by the end of the second week. In perhaps twenty per cent. the duration is three to four weeks, and the remainder run a course up to two months. With very rare exceptions complete recovery results.

Cheyrou states that after a bombardment with gas shells one may see mild cases of gassing change suddenly for worse. In this case the gas used was chloroformate of monochlorated methyl. In some subjects after gassing the prominent disturbances were digestive, in others respiratory. Whatever the symptoms they may seem so mild as to be insignificant. The sequelæ comprise cardiovascular phenomenon, cardiac fatigue, and pulmonary tuberculosis.

Although Mandel and Gibson said that the heart was slightly affected, most observers agree that among the remoter consequences cardiac symptoms are among the most prominent and may be of grave import following mustard gas poisoning. De Concilliis insists that the inflammation in the bronchioles is the most important pathological localization of the action of gases. The edema of the lungs is secondary in importance in cases in which death does not occur at once. The bronchioles contract as the gas comes in contact with them, and hence bear the brunt of the attack, while the alveoli behind are saved for a time. Treatment should be with medicated air. By this means we insure the ventilation of the lungs.

Rendu describes the lesions in the upper air passages. All are practically alike and consist of a burn of the second degree leaving white eschars, most frequently on the anterior two-thirds of the free margin of the vocal chords.

Lafont and Raux describe five cases in which the symptoms of gastric ulceration followed shortly after poisoning with mustard gas. Moutier describes six cases of appendicitis following gassing with mustard gas. Time was five to eight days, but the symptoms did not indicate serious disturbance, and they subsided under local applications.

Leporsky, reporting on the effect on the nervous system, mentions forty cases with vagotony. In some cases dissociation was seen, some parts of the vegetative system showing increased and other parts decreased tonus. The asphyxia from the gas poisoning evidently starts the centers in the medulla to extra functioning, and this in turn deranges the function of the glands with internal secretions. Other writers report different findings in regard to the nervous system. Sereisky reviewing sixty cases says that the gases contain some substance which has a direct toxic action on the nervous tissue.

Karsner reported the results of four autopsies of soldiers dead from mustard gas poisoning. One showed a mild bronchopneumonia. All showed skin burns. There was congestion of all the viscera, including in two cases the brain. The larynx, trachea, and bronchi showed severe inflammation in one case with pseudomembrane formation and in the other two with extensive necrosis of the mucosa with multiple ulcers. Two showed acute fibrinous pleurisy. All showed a bilateral bronchopneumonia with slight general edema of the lungs.

Colard and Spehl lay greatest stress upon a combination of venesection and oxygen inhalations. Among the tonics found useful were subcutaneous injections of ether, camphor, and atropine. Strophanthus seems to be the best heart tonic. Gatch recommends the intravenous use of oxygen.

The Pathology of Mustard Gas.—The symptoms appear to be conjunctivitis, laryngitis, bronchitis, and skin burns. The recognition of the symptoms is usually delayed for a considerable period, sometimes as long as sixteen hours. Warthin and Weller showed that it is an escharotic, specific in its action on the epidermis and tissues of the corium, particularly on the endothelium of the vessels. It is a chemical burn. The vessels are severely damaged and collapsed, and there is a local anemia in the earlier stages with a marked fluid exudation. The slow progressive nature of the necrosis is characteristic, the height of the necrosis being reached in from five to ten days after application. It is painless. The lesion resembles a roentgen-ray burn of the skin in that healing is slow.

Meakins and Walker issued a comprehensive report from the Medical Clinic No. 15, Canadian General Hospital, Taplow, England, on behalf of the Medical Research Committee. Two hundred cases admitted to the hospital between July 1 and December 31, 1917, were analyzed. There was no doubt of the kind of gas used in all the cases examined. Of the 200 cases, 163 were poisoned by mustard gas (dichlorethylsulphide), 33 by phosgene ($CO\ CL_2$), and 4 by chlorine.

The report dealt with the chief late symptoms, the principle reason for their delay in returning to a normal state of health, the treatment of the condition and finally the importance of irritant gas poisoning in affecting the future usefulness of the soldier.

For convenience sake the writers divided the poisonous, irritating gases used by the enemy into suffocative (chlorine and phosgene) and vesicant (mustard gas).

The suffocative gases acted mainly on the alveolar epithelium of the lungs, causing acute pulmonary edema of very rapid onset and thrombosis of the pulmonary capillaries. As a result of the edema of the lungs during the early stages, deficient oxygenation of the blood occurs unless prevented by the administration of oxygen. This deficient oxygenation of the blood then causes widespread temporary injury to various systems of the body.

In a certain number of severe pulmonary cases they concluded there was interference with the proper oxygenation of the blood, which might give rise to widely spread temporary lesions as in the suffocative group.

The chief symptoms complained of during the period of observation at the Taplow Hospital were summarized by Meakins and Walker as follows:

TABLE I.

Symptoms.	Mustard Gas. Per cent.	Phosgene. Per cent.
Cough	54	24
Pain in chest	48	60
Dyspnea	42	84
Rales	30	30
Conjunctivitis	32	..
Laryngitis	18	..
Burns	23	..
Abdominal pain	15	..
Dizziness	12	24
Tachycardia	9	24
Expectoration	10	3
Vomiting	8	6
Painful micturition	7	..
Fatigue	7	36
No complaints	4	9

Besides the symptoms caused directly by the irritative action of the gases they defined a distinct group occurring after both forms of gas poisoning but most commonly after phosgene. These symptoms consisted chiefly of dyspnea, precordial or chest pain, palpitation, fatigue, dizziness or syncope, and were commonly regarded as constituting the condition of disordered action of the heart (D. A. H.). The degree of predominance of any one of the symptoms varied with the individual. There was disturbed sleep, characterized by paroxysms of coughing, dreams, a feeling or pressure on the chest and even acute attacks of dyspnea and orthopnea.

One of the commonest symptoms responsible for retarding the patient's recovery was dyspnea, which was a frequent history from the early stages of gassing, particularly with phosgene. It occurred in eighty-four per cent. of the phosgene cases and forty-two per cent. of the mustard gas cases.

The dyspnea showed itself in different ways. Many, particularly when affected by mustard gas, complained of difficulty in breathing and showed rapid shallow respiration even when at rest. The endeavor to ventilate the lungs by increasing the respiratory rate did not permit of a further increase except with the result that extra exertion produced a greatly increased rate. This in turn was responsible for other symptoms.

Apparently the result of local action of mustard gas on the upper respiratory passages was responsible for pain and the production of a cough.

Dyspnea was less complained of after phosgene than after mustard gas poisoning, when resting. Many of the phosgene gassed cases had dyspnea only on exertion. This dyspnea on exertion was very distressing, incapacitating the patient from taking any exercise, even walking. A certain number of cases had dyspnea at night, either as increased difficulty of breathing in a recumbent position or, more commonly, showing paroxysm during sleep. Tachycardia, dizziness, and fatigue were associated with the dyspnea, more frequently in the phosgene cases, and these were the cases which exhibited typical symptoms of disordered action of the heart.

TABLE II.

Type of Dyspnea.	Mustard Gas. Per cent.	Phosgene. Per cent.
On exertion only	46	68
At rest by day	54	32
By night (usually paroxysmal)	7	36

In mustard gas poisoning cough was the most common symptom, and varied from a mild bark to an extreme paroxysm which caused patient to become cyanosed, acutely dyspneic, and greatly exhausted. Expectoration was the rule in the early stages, but had usually diminished or disappeared when the patients got to England. The nocturnal cough seemed to be the result of an attempt to take deep breaths to overcome the decreased oxygen absorption during sleep. In mustard gas cases 49 per cent. showed slight cough, 17 per cent. severe cough, and 34 per cent. nocturnal cough. In phosgene gas cases almost exactly the same proportions were shown.

Pain in the chest was a general and distressing symptom even after the acute stage had passed, and increased with attempts to breathe deeply. Pain localized in the left breast, or precordial pain, was most common after phosgene gas poisoning and was often alarming to the patient; it was likely to be greatly aggravated by exertion and might be acute even during periods of rest. The skin over the site was usually extremely hypersensitive.

In cases of mustard gas poisoning 30 per cent. of the cases showed large moist and dry rales, indicating that the larger air passages were involved. Crepitations were seldom found. On the other hand, 30 per cent. of the phosgene cases showed fine crepitant and sibilant rales, indicating involvement of the smaller bronchioles and alveoli. A few cases which showed D. A. H. on arrival in England developed during late convalescence from irritant gas poisoning an asthmatic condition of the lungs.

Most cases showed some involvement of the larynx varying from a slight huskiness to complete aphonia. Unless there was direct evidence of the definite involvement of the mucous membrane or vocal cords, the condition was considered to be functional. Conjunctivitis was a common feature. With a few days' rest and treatment signs of acute inflammation soon completely disappeared.

Disturbances of the skin, varying from simple erythema to extensive ulceration, occurred in cases affected by mustard gas. The principal parts involved were surfaces likely to be moist, such as the flexor surfaces of the joints, groin, genitals, chest and back.

In phosgene gas poisoning vomiting occurred to some extent during the early stages, but this was a constant feature in mustard gas cases. In from 6 to 8 per cent. of both types this persisted and usually occurred after taking food. Excitement and worry usually increased the frequency of the vomiting even after long periods of freedom from it. *X*-ray examination after bismuth meals showed the stomach and duodenum to be normal in shape, size and motility. Epigastric pain was frequent in mustard gas poisoning, always above the umbelicus.

Meakins states that in cases of phosgene gas poisoning particularly there was a distinct neurotic tendency. This he attributed to the direct action of phosgene on the alveolar epithelium of the lungs, causing an acute pulmonary edema and resulting in an acute want of oxygen throughout the body. This lack of oxygen caused widespread temporary injury, to the nervous system particularly. The interference of deep breathing during the acute stages also resulted in a lack of oxygenation of the tissues. The mental effect of gas poisoning through

seeing the effects upon others he also thought to aid in the production of neurotic symptoms.

Treatment.—Mild burns were treated with boracic ointment; deep burns, which were usually injected with hot boracic fomentations. Sometimes in cases of deep, extensive burns the patients were submerged in hot alkaline baths and the patient left there for twenty to thirty minutes after the dressings had floated off. The bath was soothing and cleansed the affected areas, which were protected by liquid paraffin dressings.

Damaged eyes were irrigated with warm alkaline solution, followed by instillation with liquid paraffin, and protected from the light by a shade or dark glasses. Much of the aphonia was of neurotic origin and required appropriate treatment. Cases of recovered bronchitis and bronchopneumonia without elevation of temperature were got out of bed as soon as possible and encouraged to walk and mix with other patients.

Cases with gastric symptoms were most difficult to deal with; they were largely neurotic and relapsed frequently just before discharge from hospital, or after discharge, necessitating their readmission to other hospitals for exactly the same treatment. Rest in bed was harmful and occupation with physical training effective in mild cases. In general when the treatment of symptoms was approached from the viewpoint that they were largely neurotic the cases improved rapidly and usually completely.

Cases of disordered action of the heart were common and were treated by keeping the patient in the open air and encouraging him to take graduated physical exercise until he could walk without distress.

It was estimated that 77 per cent. of the mustard gas cases were discharged from hospital before the end of the seventh week, while only 43 per cent. of the phosgene cases were discharged in that time. The symptoms that were responsible for the stay in hospital of more than seven weeks were those of the D. A. H. group of which dyspnea was the most important symptom.

Cases Discharged.—Eighty-one per cent of Meakins' cases of mustard gas poisoning were discharged to duty; three per cent. were discharged as permanently unfit for further military service. It was exceptional for a case of mustard gas poisoning to be permanently unfit for further military duty as the result of the direct action of the gas.

Fifty-one per cent. of Meakins' cases of phosgene poisoning were discharged to duty. Thirty per cent. were discharged as permanently unfit, mostly from D. A. H. and neurasthenia. In both groups the permanently unfit Meakins ascribes to the initial "oxygen want" which had caused the damage to the tissues. Three cases of 1915 chlorine gas poisoning, which is a suffocative, were discharged from the same hospital as permanently unfit, one suffering from D. A. H. and two from pronounced bronchitis and emphysema.

All cases under investigation during this period were followed for three months after discharge from hospital. The information sought was the patients' eventual classification, their physical fitness as soldiers, and such physical signs or symptoms as interfered with their performance of full duty. About 75 per cent. of the mustard gas cases discharged were estimated to be fitted eventually for full military duty. In the phosgene cases 30 per cent. were found to have been discharged as permanently unfit, 15 per cent. had been lowered in category, and 6 per cent. were still under treatment, showing that phosgene had a high disabling power as compared with mustard gas.

The most striking feature of the cases followed up was the great prevalence of chronic respiratory disorders such as "chronic bronchitis" or dyspnea associated with other symptoms of D. A. H. and the frequency of vomiting.

Speaking generally it is very difficult to draw any definite conclusions or make any tabulations as to the final results in cases of gas poisoning. At first it was feared that gassed cases, particularly with chlorine, would develop tuberculosis, but there is no evidence available to show that there is a greater proportion of cases of tuberculosis among returned men who have been gassed than among those who have not.

The heat of a Canadian midsummer affects cases of mustard, and presumably phosgene, gassed cases quite markedly. The breathing becomes shallow and rapid and the feeling usually described as "all in" is general. But since most of the gassed cases on discharge disappear to their homes all over the country it is out of the question to draw any general conclusions as to what extent they have been permanently damaged. Until through the efforts of the Army Medical authorities or the Pensions Board data on a large number of gassed cases is gathered we will have no great volume of information upon this phase of the subject, though the excellent analysis of Meakins and Walker of 200 cases will probably be found to hold good in a larger number of cases. What the ultimate results of gassing will be in shortening the life period and its efficiency we have no method of gauging.

Medicolegal Notes.

Expert Evidence—Objective and Subjective Symptoms.—The Illinois Appellate Court holds that a physician who has treated an injured person and three years later makes an examination for the purpose of qualifying as an expert to testify as to the then condition of the patient, must base his opinion upon objective, not subjective, symptoms. A physician who has not treated an injured patient at all and who makes an examination for the sole purpose of qualifying as a witness as to the patient's injuries may not testify as to objective symptoms.—Horstman v. Chicago Rys. Co., 210 Ill. App. 144.

Cause of Pneumonia.—In a servant's action for injuries alleged to have produced traumatic pneumonia, a physician testified that the accident did not cause the disease. It was held that an argument giving an illustration of a man so injured, who did not know he had pneumonia, which eventually killed him, was not improper.—Arkansas Central R. Co. v. Goad, Arkansas Supreme Court, 206 S. W. 901.

Hypothetical Questions.—In a murder case hypothetical questions asked a physician witness did not fairly state the evidence, omitting evidence in some parts and exaggerating it in other parts. The Oklahoma Court of Appeals held that the doctor was properly not permitted to answer these hypothetical questions, stating the rule to be that hypothetical questions which do not include all of the material testimony, or which include matters not in testimony before the court, should not be propounded to expert witnesses.—Davis v. State (Okla.), 177 Pac. 621.

THE ETIOLOGY OF YELLOW FEVER.

YELLOW fever has been very thoroughly studied over a long period of time and numerous facts concerning its epidemiology have been learned. We are familiar with its symptoms and the way in which it is transmitted. Based upon this information methods have been adopted which have prevented its introduction into this country and which have practically eradicated it from localities in which sufficient control could be exercised. All of this has been accomplished without a knowledge of the organism which is the cause of the disease. The demonstration of the relation of the mosquito to yellow fever was one of the most brilliant achievements of scientific medicine and pointed the way to effective prophylactic measures against one of the most terrible afflictions of tropical countries. Numerous attempts have been made to determine the actual cause of the disease but they have been uniformly unsuccessful up to the present time.

Last year a new study was undertaken by The Yellow Fever Commission of The International Health Board and it appears that their work has met with success. Noguchi has presented (*Jour. Exp. Med.*, 1919, xxix, 547, 565, 585; and xxx, 1, 9, 13) a report of the experiments which were undertaken by him and the observations which he made in the course of this study. The cases were studied at the Yellow Fever Hospital in Guayaquil and were found to present clinical and pathological features which conformed with those described by other investigators of the disease as it occurred in other places. Difficulties were met in the attempt to transmit the disease to animals. Nearly twenty kinds of animals were employed and with only one, the guinea pig, was it possible to obtain positive results. It is possible that some of the other animals suffered a mild or atypical form of the infection but apparently none were sufficiently susceptible to enable the virus to multiply and produce lesions and symptoms. Guinea pigs proved to be rather sensitive, though often they presented no obvious reaction. The reaction was obtained by the intraperitoneal injection of fresh blood obtained from the patient early in the disease and resembled, both clinically and pathologically, yellow fever as seen in man.

In the blood, liver, and kidneys of the guinea pigs thus experimentally infected there was demonstrated a minute organism which resembled the *Leptospira icterohæmorrhagica*, the causative agent of infectious jaundice. Noguchi proposes the name of *Leptospira icteroides* for this organism and is of the opinion that it is the causative agent of yellow fever. The argument in favor of this contention is briefly as follows: (1) Guinea pigs may be infected by injection into the peritoneal cavity, the blood stream, or the subcutaneous tissue, by feeding, or by application to the skin or mucous membranes of infected tissue or culture. (2) The disease produced in these animals resembles, clinically and pathologically, yellow fever as seen in man. (3) The organism may be isolated in what is apparently a pure culture and later generations of this culture, carried on artificial media, will reproduce the disease in guinea pigs. (4) Guinea pigs that have recovered from inoculation with the culture are resistant to subsequent infection with the blood of patients. (5) The serum of men convalescent from yellow fever contains a substance which gives a positive Pfeiffer phenomenon with this organism and is able to protect guinea pigs against doses of infection which would otherwise have proved fatal. (6) The organism may be isolated by direct cultivation from the blood of patients and may be found in sections of the liver and kidneys.

It would be going too far at this time to say that the pathogenicity of this organism is definitely proven. There is a possibility of a granular phase in its existence and it has been shown that the clear filtrates obtained from the emulsion of the liver and kidney of an infected guinea pig are themselves capable of producing the infection. Nevertheless it seems not improbable that this organism is actually the causative agent of yellow fever. Experimental work dealing with the stegomyia mosquito has not yet been reported. It is to be hoped that the author will be able to complete his work and thoroughly to substantiate his theory, for he then will have made a notable contribution to bacteriology.

FEMORAL HERNIA IN WOMEN.

MOST modern textbooks state that femoral hernia is more frequent in women than in men, and that in the former the hernia is smaller, and therefore is more prone to strangulation. Kotzareff, assistant at the Surgical Clinic at Aaran, believes that this classical teaching should be further completed by the study of the factors giving rise to this type of hernia in general, and above all to right-sided femoral hernia in women. The statistics and personal observations of Kotzareff go to show that femoral hernia in women is more frequent than in men because the femoral canal in the former is larger and the vessels going through it are smaller. Re-

peated labors, by distending the abdominal parietes, result in relaxation of the parietal and visceral peritoneum, in consequence of which a hernia is more readily produced. On the other hand, the uterus and bladder appear to combine in forcing the intestines to the right and left, and the pelvis, which is broader in women, offers more room for the intestinal mass and omentum to slide over to the sides and thus to become more distant from the inguinal canal. The structures composing the contents of a femoral hernia almost invariably pass under the Fallopian ligament into the prepubic space formed by the ligaments from their attachment to the pubic bone.

Kotzareff next inquires why femoral hernia is more frequent on the right than on the left side, and then formulates the following sage remarks: The insertion of the mesentery, which extends from the second lumbar vertebra to the cecum, therefore having an oblique direction from left to right, contains within its grasp a large portion of the small intestine on the right, for which reason the greater omentum evidently becomes directed much more to the right than to the left, as the author referred to has been able to note both by laparotomy and necropsy.

A viscus the size of the liver, which weighs upon the right kidney and right colic angle, will likewise play an important part in forcing the viscera contained in this cavity from right to left, therefore toward the weaker structures, when the contraction of the abdominal muscles, not overlooking the diaphragm, comes into play.

Women in general, like their brothers, are right-handed; the right-sided musculature consequently works relatively more than the left musculature; therefore, in the majority of Kotzareff's patients, who were peasants, the efforts which they made to carry out their agricultural work were more considerable on the right than on the left side. The sigmoid flexure being on the left, is much less movable than the right-sided cecum; consequently, the latter viscus enters the femoral canal on the same side with much greater ease, bringing down the omentum and an intestinal loop along with it. During pregnancy the uterus is more apt to be tilted to the right than to the left; the abdominal parietes are for this reason more tense on the right side, and the external iliac vessels are more compressed on this side. The result is stasis in the femoral veins and a dilatation of the femoral canal. After labor, the right half of the abdominal parietes and peritoneum remains weakened, while the right femoral ring is enlarged after the vessels which put it on the stretch have returned to their normal caliber. The greater the number of labors, the more numerous will be the causal factors facilitating the production of right-sided femoral hernia.

THE PROGNOSIS OF TERTIARY SYPHILITIC EPIDIDYMITIS.

Two problems present themselves to the clinician when formulating the prognosis in cases of tertiary luetic epididymitis, viz., is this particular lesion a symptom of severe syphilitic infection, and, as a local process, is its prognosis bad, and will it or not compromise the genital functions? In some instances the gumma in the epididymis has coincided with serious tertiary lesions elsewhere, such as a gummatous osteomyelitis or pulmonary syphilosis, while in one case the epididymitis appeared eighteen months after the appearance of the initial sclerosis, along with a gumma of the left cheek, which would seem to solve the first question affirmatively.

Clearly, a malignant tertiary syphilis may, among its multiple lesions, give rise to a gumma in the epididymis, and, all things considered, a patient with this luetic localization is probably more prone to develop a serious visceral manifestation involving the brain, lungs, or liver. But if the soil is already prepared, if the epididymis has been rendered more vulnerable by some former pathological change—gonorrhea or trauma—the structure resists the luetic poison weakly, the localization occurs even when the syphilitic virus is not very active. For this reason it is not logical to conclude that because there is a tertiary lesion of the epididymis the syphilis is, of necessity, of unusual intensity.

As a local lesion, tertiary epididymitis is unquestionably benign from the viewpoint of prognosis. The product of ejaculation not having been analyzed in any case with which we are familiar, we are prevented from affirming that the duct of the epididymis may become patent after the disappearance of the infiltration which occluded its lumen or compressed its walls. However, if the facility of resolution by proper treatment is not a sufficient guarantee, it is quite enough to say that in all the published cases the lesion has been unilateral. Therefore, the uninvolved organ will be patent, and thus assures the preservation of the genital functions.

Clinically, a *restitutio ad integrum* can be obtained, providing energetic treatment is resorted to in time. This has been the invariable outcome in the vast majority of cases when antiluetic treatment was begun at the onset of the epididymitis. On the other hand, in certain instances a small sclerous nodule has remained even when treatment was commenced at the onset of the process.

Without any doubt, when the cicatrix which follows the gumma has ceased to be a syphilitic lesion, and has become an ordinary cicatricial sclerous tissue, there is naturally no hope left that the destroyed structures will regenerate and recover their functions, no matter how energetic or prolonged the treatment may be.

It is none the less true that if a tertiary epididymitis arises during the progress of a severe syphilis, it has unquestionably a benign prognosis, and to it may be correctly applied what the French school says of syphilitic neoplasms in general, viz., "When an epididymitis is present, happy should be the bearer if he has had syphilis."

The Treatment of Malaria.

Malaria offers comparatively few problems to the physician in the northern portion of this country

beyond that of persuading the patient to continue the treatment for a sufficient length of time. In tropical and subtropical climates the situation is quite different and the treatment of patients suffering with this disease becomes one of the most difficult tasks of the practitioner. This is wholly aside from the problem of prevention, screening and drainage, which is essentially the same in all localities. In the British Expeditionary Forces in Macedonia and Salonica, malaria assumed a position of great importance and the story of how one man coped with the task is told in Alport's book.* The number of cases of cerebral malaria and of serious complications was unusually high and yet the results he obtained were unusually good. The story is that of one man, written often under the difficult conditions of the front line and always without access to the literature, and necessarily assumes a somewhat dogmatic tone at times. Alport found that his results were uniformly good when he used quinine in sufficiently large doses and claims that the dosage is the only secret of the treatment. Using the bihydrochloride because of its great solubility he administered it intravenously, intramuscularly, and by mouth in doses up to 100 or 120 grains a day when the need was urgent. The remarkable success of the treatment is indicated by the fact that thirteen cases of cerebral malaria, occurring in 2000 cases of the disease, all recovered, though the mortality before that time had been as high as 57 per cent. His story is backed by numerous case reports and a number of photographs. He confesses his inability to affect the crescents of estivoautumnal malaria with any treatment which he tried. These results conform with the most recent publications from this country which also insist that quinine is the only drug needed to bring about a cure in malaria and that its intelligent use will practically always be crowned with success. This work is one of the interesting and valuable contributions from the medical work in the Great War and shows again that the most uncomfortable surroundings and extreme inconveniences are not necessarily a bar to good work.

Alienation Among the Primitive Peruvians.

According to an article abstracted in *El Siglo Medico* of May 24, the Incas had considerable knowledge of alienation. The original sources of information are not stated, but doubtless include native pottery, etc., reinforced by the testimony of the early conquerors. They knew of congenital as contrasted with acquired forms of alienation. Of acute types, they were aware of febrile delirium and alcoholic delirium. Much less has always been said of the use of alcohol by the Peruvians than by the old Mexicans. Cocainism has always been regarded as the national vice of the Peruvians, and naturally they were quite familiar with its action on the psyche. They also knew of the deliriant action of stramonium. There were epidemics of dancing madness there, as in medieval Europe, and these were curable by psychotherapy in the form of enchantment. A class of people who went in for refinements of sexuality were also treated by the same measure. Curiously, the original writer designates these subjects by the English word "snobs," perhaps used in the archaic sense of person of low standing. Inverts or perverts can hardly be called snobbish, but they are often markedly affected, as shown by the common tradition that the introduction of forks as a substitute for fingers was due to Parisian homosexuals.

*Malaria and Its Treatment in the Line and at the Base. By Capt. A. Cecil Alport, R.A.M.C.(T.), M.B., Ch.B., Edin. Price $6.00. New York: William Wood & Company, 1919.

News of the Week.

Transfer of Speedway Hospital Postponed.—Secretary Glass has not taken over the Speedway Hospital in Chicago though he was "directed" by a mandatory decision in the General Deficiency bill to take over the hospital for the Public Health Service. The architect of the Treasury estimated that it will cost $1,900,000 more than the $2,000,000 already appropriated for the purpose of remodeling the building. Edward Hines, the owner of the hospital, has been notified that he is at liberty to turn it over to the city of Chicago, to religious control, or otherwise.

Hospital Gift Declined.—At a meeting of the Board of Estimate of New York City resolutions recommending the acceptance of the offer of the Rockefeller Foundation to turn over to the city the War Demonstration Hospital located on the grounds of the Rockefeller Institute and to remove the buildings at the expense of the Foundation to whatever site might be chosen were considered. Mayor Hylan and Comptroller Craig prevented the Board of Estimate from accepting the gift for the time being. The offer was made through the efforts of Health Commissioner Copeland, who was desirous of having the buildings removed to Warwick farm, which the city maintains for the care of inebriates. A great deal of the opposition to accepting the hospital seemed to hinge on fact that it was proposed to use it for the treatment of drug addicts by the Department of Health in cooperation with the Narcotic Drug Commission.

Antityphus Army Starts for Poland.—A group of five hundred and fifty American army officers and volunteers, all sanitary experts, under the command of Col. Harry L. Gilchrist of the Medical Corps, U. S. A., has left Paris for Poland, where an effort will be made to eliminate typhus fever from the military camps. American and British army authorities have sold Poland the larger part of their delousing equipment, and the Polish Minister of Health is gathering all such equipment left behind by the Germans. Eight hundred railroad cars and seven hundred motor trucks will be required to transport the equipment and chemicals of the American expedition. Typhus fever is said to be epidemic from the Baltic to the Black Sea.

Dr. Nikolas Berend, a member of the faculty of the University of Budapest and widely known as an authority on children's diseases, was killed recently during an attempt to overthrow the Soviet Government in Budapest.

Dr. Emil Fischer, professor of chemistry in the University of Berlin, died on July 15. Professor Fischer was known through his contribu-

tions to organic and biological chemistry. For his work in chemistry he was awarded the Nobel prize in 1902. He was awarded the Elliott Cresson gold medal by the Franklin Institute of Philadelphia in 1913. Dr. Fischer was born in 1852 and educated at Bonn University.

Lieut. Commander W. B. Brinsmade of Brooklyn has been cited by General Pershing for meritorious and conspicuous service in the A. E. F. Dr. Brinsmade organized Naval Base Unit No. 1, which left the United States in September, 1917. The Unit took care of 3,668 battle casualties and 504 cases of pneumonia.

Major Albert Garvin, formerly superintendent of the New York State Hospital for Tuberculosis at Ray Brook, N. Y., who served as chief of the Bureau of Tuberculosis, Medical and Surgical Department, with the American Red Cross forces in France, has been decorated with the Medaille d'Honneur de Vermeil of the French Government in recognition of his services to that country.

Tuberculosis in French Army.—During a discussion in the French Senate on a bill to establish tuberculosis sanatoriums, it was stated that 25,000 French soldiers had died of tuberculosis during the war and 120,000 men were exempted from service because of the disease.

Renew Narcotic Drug Crusade.—The Federal Government has begun a new crusade in New York City to stop the illegal traffic in narcotic drugs. A number of drug stores have been raided and pharmacists and physicians have been arrested. The State Narcotic Drug Control Commission has recently given a hearing to seven physicians and three druggists charged with violating the Whitney drug control act. Four of the physicians were from New York City, one from Buffalo, one from Ithaca, and one from Glen Falls. The three druggists were from New York City. No definite action was taken in any of the cases, decision being withheld. Most of the charges were based on failure to observe the technical points of the law as to the use of official forms and the signing of prescriptions.

War Emergency Measures Become Permanent.—Notification has been received at the American Red Cross Headquarters from the officials of the Seine-Inferieure, a section embracing 2,000,000 people, that they have taken over and provided for the permanent maintenance of an organization for the protection of mothers and children, installed by the Red Cross last year. The emergency organization in the prefecture of which Rouen is the center, which was established by Dr. Walter R. Ramsey of St. Paul, has become permanent. It includes a model clinic for children, prenatal clinic, dental clinic, school for social service workers, courses for midwives, school teachers and students, a maternity hospital capable of eventually accommodating 1,600, a school for children accompanying prospective mothers, children's hospital, and a model dairy farm. In recognition of his services the officials of the prefecture of the Seine-Inferieure presented Dr. Ramsey with a gold medal. He received another gold medal from the city of Rouen.

The New Birth Registration.—It may be recalled that the New York State Legislature at its last session passed a new birth registration law. Printed forms are now being prepared in accordance with the new regulations by Dr. Hermann M. Biggs, State Commissioner of Health. For all births occurring since April 14, 1919, the forms will give the name of the child, the date and place of its birth, the names of the parents, and the signature of the registrar who signed the birth certificate. The importance of birth registration is again urged.

Obituary Notes.—Dr. B. A. McConnel of Dover, Ohio, a graduate of Perdue Medical College, Indianapolis, died after a long illness, in a local hospital, on July 8, aged 55 years.

Dr. Oliver Barney, a graduate of Tufts College Medical School, 1912, died in the Boston City Hospital from injuries sustained in an automobile accident on June 25, aged 31 years. He served as junior lieutenant in the navy during the war.

Dr. John Peck Brooks of Oneco, Conn., who studied medicine in New York City and later in Nancy, France, died in Providence, R. I., on July 13, aged 75 years.

Dr. William Henry Price of Swarthmore, Pa., and Point Pleasant, N. J., died at Jefferson Hospital, Philadelphia, on July 3, at the age of 54 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1889. He was for a time instructor in diseases of children in his alma mater.

Dr. Silas G. Hertz died at Philadelphia on July 7, at the age of 87 years. He was graduated from the Medico-Chirurgical Hospital in the class of 1889.

Dr. Ellwood Beatty Warner died at Philadelphia on July 16 at the age of 60 years. He was graduated from Jefferson Medical College in the class of 1882.

Dr. Herman Eichhorn, a graduate of the College of Physicians and Surgeons, in 1904, died at his home in New York City, on July 13, aged 38 years.

Dr. Mary A. Willis, a graduate of the New York Eclectic Medical School, in 1886, died at her home in Jersey City, on July 13, aged 75 years.

Correspondence.

FOR THE REPEAL OF THE NARCOTIC DRUG LAW.

To the Editor of the Medical Record:

Sir:—The deplorable conditions attending the enforcement of the State narcotic drug laws in this city, through the combined action of the Narcotic Drug Commissioner and the local Department of Health, have led to the organization of an association of medical men under the title of the American Federation of Physicians, to request a repeal at the earliest possible date of the law for a narcotic drug commission in this State. This organization is intended solely and primarily to protect its members from the enactment of unjust and harassing laws restricting the legitimate practice of medicine. This step was not taken until every effort had been exhausted to compel the organized medical bodies, both local and State, to live up to the articles of their constitutions, whose purposes are "to secure

the enactment and enforcement of medical laws; to promote friendly intercourse among physicians, to guard and foster the material welfare of its members, and to protect them against imposition and to direct and enlighten public opinion in regard to the great problems of State medicine."

Not only have all such obligations been ignored by the organized medical bodies of this State, but many of the efforts of individual members, acting in harmony with the principles thus stated, have been thwarted by lack of support on the part of those responsible for the control of these organizations. This was demonstrated at the meeting of the House of Delegates of the State Society, May 20, 1918, in refusing to pass the resolutions supporting objections to the present law.

This attitude was emphasized during the present crisis in the address of Dr. Alexander Lambert, president of the American Medical Association, at the meeting of its House of Delegates at Atlantic City, June 9, 1919. Speaking on the subject of narcotic addiction, he says: "These laws are making it more and more burdensome for physicians using narcotics legitimately, but that is a mere annoyance. The responsibility on the medical profession is becoming greater and greater to see to it that some action should be taken against a few renegade and depraved members of the profession, who, joining with the criminal class, make it possible to continue the evil and illicit drug trade. . . . The second class comprises those who are victims of some incurable morbid process giving incurable pain. To these people a narcotic is a necessity, and they should be treated openly and frankly, and be given the drug in the amount necessary for their relief. They should be known to all physicians franked by a health department, and the amount for their comfort stated, with interstate reciprocity between health boards, and, if necessary, definite places stated to which they could go and obtain the required amount of their drug by showing their certificate without being preyed on and mulcted by dishonest purveyors of narcotics."

All this is in support of the allegations by lay abettors of the drug laws now in existence, and of a system of registration under these laws of drug addicts, which heretofore has been applied only in the case of convicted criminals. The need to-day is for a body made up of the members of the medical profession acting in harmony for the purposes in which our organized medical bodies have so signally failed, namely, the protection of the rights and professional interests of its members. This duty the American Federation of Physicians hopes to perform. It asks the aid and support of the practitioners of this State by enrollment among its members.

JOHN P. DAVIN, M.D.,
Secretary.
117 WEST SEVENTY-SIXTH STREET, NEW YORK

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, July 11, 1919.

The Position of Temporary Officers in the Royal Army Medical Corps.—There has been, and still is, considerable mystification as to many of the points in connection with the terms of the recent offer by the War Office to engage the temporary officers in the Royal Army Medical Corps for service with the Army of Occupation. Last week the Director General of the Army of Medical Services issued an invitation to medical practitioners, including those who have already served, to undertake the duty or further duty with the Army of Occupation under conditions which were felt to be a little nebulous. The offer stated that candidates who have served would be further commissioned with the confirmation in their previous rank, while the medical recruits to the Army of Occupation would be commissioned primarily as lieutenants. The pay, £550 a year, was to include all allowances, or rations in lieu of some portion thereof, while outfit and money for kit would be provided for the new men. The period of engagement was to be for one year, or until the need for service disappeared, whichever of these two events should occur first. It was clear that the Director General of the Army Medical Services could not prophesy that the duties of the Army of Occupation would come to an end within a year, so that behind the scheme there must have lain some intention to institute a service by shift or rota.

But while that point was necessarily left open other and more concrete circumstances have been felt to call for further details and Sir John Goodwin has now issued the following explanation: (1) Officers who are at present serving in the Royal Army Medical Corps under contracts for 12 or 6 months or other definite stated periods will be required to complete these engagements, with the option of entering into the new contract on termination. (2) Officers who are serving under contracts "until the termination of the present emergency" will be eligible for demobilization on the statutory date for the end of the war which will be published, and the gratuities payable under such contracts will be issuable on that date. (3) All officers who are at present serving may offer themselves for services with the Army of Occupation (such service to commence on the day following the completion of their present contracts) under the terms of the recent offer—namely, for a period of 12 months or until their services are no longer required, whichever may happen first, at a salary of £550 per annum plus rations or the allowance in lieu. The sum mentioned is inclusive of both bonus and gratuity, and no additional emoluments of any kind are issuable. (4) Officers holding the acting rank of lieutenant-colonel or major will be required to sign a contract embodying the above terms, but will draw the pay and allowances of their acting rank whilst holding it, the contract terms as to emoluments remaining in abeyance during that period; they will revert to contract rates on ceasing to hold the acting rank. (5) Field officers of the Territorial Force and Special Reserve will receive the pay and allowances of their substantive field or acting rank. (6) Officers will continue to draw children's allowance for the present. The terms are obviously fair, and the invitation ought to meet with many responses, for the difficulty and doubt in which many young medical men find themselves for the moment in

regard to their future, are very real. I have sketched their position below.

The Future of General Practice.—There are at the present moment in the country a very large number of young medical men at a loose end. Many of them are full of new experiences and they find on all sides opportunities for bringing those experiences to market in such quantity that they have a right to obtain good terms. It is perfectly clear that the ministry of health will shortly have in its gift a large number of administrative or sub-administrative posts, carrying regular salaries, which will be graded not only in accordance with the importance of the responsibilities incurred but in accordance with the time to be taken up; for it is presumed that many of these posts will necessarily be part time offices. On the other hand reorganization of panel practice, which in some directions is imminent, will certainly place at the disposal of young medical men many chances of obtaining an assured livelihood and good scope for general or special clinical knowledge where the panel practice, over and above the flat-rate payments of subscribers will bring with it a paid appointment the aggregate emolument would make the young medical man far better paid at the opening of his career than his father or his grandfather could ever have expected to be. Hitherto the one great and condemnatory criticism of the position has been that while the start is so good the future holds no greater promise. The posts held at first will not later carry a higher salary, so, unless some flexible system of promotion is laid down the comparatively inexperienced man will receive as much money as his senior; the income from panel subscribers can only go up if the practitioner increases the size of his panel, and while for physical reasons this is an impossibility above a certain figure, for no reasons whatever can it be alleged in these days that a man as he grows older will command a larger public confidence. Justifiable comment on the position has always been that the good start does not necessarily insure the good future. The meaning of this is that general practice in this country, as we have hitherto understood it, is absolutely in the melting pot. In a few years time there will no longer be a group of family practitioners having a monopoly of the health of certain districts, each of them supposed to epitomise all the medical and surgical wisdom required in that district, save where state medicine, through the old Local Government Board or the Board of Education, must annex a portion of the burden and therefore of the remuneration. But the destruction of these monopolies will go hand in hand with added opportunity both for specialization and for the passage from the ranks of general practice to that of hospital surgeon and physician and scientific expert. For as there will be no segregated class of general practitioner, so there will be no segregated class of hospital officer and scientific expert. The provincial hospitals, becoming centers of scientific medicine in their localities, will be officered by men who by fusion of duty with the general practitioners of the neighborhood will make of the whole of the medical officers one general scheme for the good of the populace. The medical men of the district will have beds in their own hospitals, and will receive for their patients the consultative advice of their fellows, and the assistance supplied by a laboratory of chemical research. This is rather the picture of the future; the difficulty of the present is to induce young men to settle down in general practice, believing in the inevitable of these developments. They have seen many things and done many things, and they find the prospect not only doubtful but humdrum. The various services should therefore find that they have a great choice among them, and the question of emolument becomes a delicate one. The young men wish to enter the service, but not if the pay and prospects remain bad; the service must have the young men, but pay is never raised when there seems a likelihood of competition for employment. Day by day it becomes evident that some form of medico-political union is becoming a necessity for the medical profession, and day by day the question becomes more important whether the existing British Medical Association can reform itself into the necessary body, or whether the newly formed medico-political union will be useful, or whether the larger general scheme of federated interests expounded by the Medical Parliamentary Committee will be found the simplest step, if only as a preliminary, to be taken at the moment.

British Science and University Training.—The British Science Guild is holding at the present moment in London a very stimulating and informing exhibition of British scientific industries, illustrating recent progress in industrial manufacture mainly by a display of the new products turned out by various firms in response to the needs of war, and mainly to supply the deficiencies caused by a break with Germany. The exhibition is being held at the Central Hall, Westminster, and affords an opportunity to men of science, to manufacturers, and also to the public of stimulating the fine work done during the past four years by general and special commercial firms, especially in their connected laboratories. A similar but far less intensive exhibition was held last year when success encouraged the very active Guild to make a greater display contemporary with the arrival of a definite though still rather disturbed peace. And in the new era the exhibition has been designed not only to show the advance in science and invention but to bring together the evidence for the belief that many activities, planned at the time as make-shifts to supply the urgent needs of war, are designed to become the permanent and staple source of national enterprise and wealth in the future. Here it is that the great research laboratories of the older universities have proved so fruitful in resource, and it is a moving thought that the great institutions planned in the thirteenth or fourteenth centuries for the diffusion of knowledge should be found playing their rôle in a practical manner in the twentieth century. Until 50 years ago—some women say until the actual arrival of the twentieth century—Oxford and Cambridge were held to be following in reactionary spirit too closely to their mediæval lines. In Plantagenet

and Tudor times men were forced to hark back to the Roman and Greek civilization for their wisdom and culture; science had stopped short with the wonderfully prophetic but wholly inadequate prognostications and statements of a handful of veterans, but the pages of the classics revealed all the wonders of arts and philosophy. From Greek, Roman, and Arabian science there seemed no definite paths of progress; from the literature of the first two countries there emanated an ever splendid and ever vigorous incentive. So the ancient universities taught the "humanities" by which word they sought to establish the claim which they made for classical knowledge to contain the epitome of human wisdom. When science began to find her own, and Luther destroyed the dignified but iron-bound precepts of the Christian Church, and a mass of freed thinkers began to demonstrate the essential physical truths, the older universities were slow to assist the workers, and were obviously prepared to abide in their mediæval creed that the progress of the world should be ensured by familiarity with the tenets of Plato and Aristole, Cicero and Pliny, with the epics of Homer and Vergil, and with the elegancies of Hesiod and Tibullus. It has taken 200 years to break down their faith, but today we find the finest expositions of practical science emanating from Oxford and Cambridge, and sister university establishments, whose later foundation enabled them from their start to be free from the shackles while profiting by the experiences of their seniors. The wealth of products shown at the exhibition of the British Science Guild is an evidence in many directions of the capacity and skill of the British manufacturers in acquiring new industries and in restoring old ones on a scientific basis, but it is also an evidence of the eternal truth that wisdom is prolific, and that energies of learning stored in one direction can be transformed into great performances in another direction. The success achieved by men trained at university laboratories in mechanical science, in the manufacture of textiles, electrical appliances, and glass tell their story eloquently, and in a more concrete way than any of the greater discoveries in medicine, chemistry, and agriculture can tell it. The learning of our older universities, while retaining in one set of schools its relation with the magnificent past, is now, in another set of schools, switched off to the immediate and common needs of the people.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, June 28, 1919.

American Memorial Hospital for Rheims.—The American Fund for French Wounded has decided to give, as a permanent memorial of its work in France during four years of war, a completely equipped and endowed hospital to the city of Rheims. This hospital will have a capacity of one hundred beds. The initial cost will be $100,000. At present a temporary hospital is being operated at Rheims, in the rue Chanzy, near the Cathedral, in conjunction with the Women's Overseas Hospitals, for the benefit of returning refugees. The site of the permanent hospital will be given by the Municipality of Rheims.

Closing American Hospitals in the Occupied Area.—Further elimination of units from the Army of Occupation is reported by the medical branch of the Third Army Headquarters. Within the past few days orders have been given for the return to the United States of the staff of Evacuation Hospitals No. 9 and 22, both located at Coblentz, and the personnel of these institutions will be on its way to embarkation centers before the end of the month. This will leave Hospitals Nos. 16, 27, and 49 in the forward area. At Treves, Evacuation Hospital No. 12 has been closed and the patients transferred to No. 19, while No. 13, in the City of Luxembourg, is now packing its stores and equipment ready for return to the S. O. S. before the end of the month.

Appointment of Dr. Strong.—The Director-General of the League of Red Cross Societies, Sir David Henderson, announces the appointment of Colonel Richard P. Strong, Medical Corps, U. S. A., as Acting Director of the Bureau of Hygiene and Public Health of the League. During the war Colonel Strong served in Serbia in 1915, as Director of the American Red Cross and International Sanitary Commissions, in connection with the suppression of typhus. As a member of the American Expeditionary Forces, he was associated with the Department of Infectious Diseases of the Chief Surgeon's Office. He is a member of the Inter-Allied Sanitary Commission and has directed the American Commission's research investigations in trench fever.

Red Cross Nurses in Greece.—Eight nurses of the American Red Cross were decorated recently by King Alexander of Greece with the medal of Military Merit for their work in fighting the typhus epidemic in Macedonia. The eight nurses are Sara Addison of Baltimore; Marie Glauber of Chicago, Ill.; Alma Hartz of Davenport, Iowa; Isabelle Martin of San Francisco, Cal.; Emily Porter of Bridgeport, Conn.; Clarissa Blakeslee of Drexel Hill, Pa.; Edith Glenn of Bristol, Pa.; and Florence Stone of Plainfield, N. J. One of the nurses, Miss Blakeslee, was herself stricken with typhus during the epidemic, but has now entirely recovered. In making the presentation, King Alexander spoke of the ravages of typhus in Macedonia and registered his gratitude to his American Allies for their work in combating it.

LETTER FROM CANADA.

(From an Occasional Correspondent.)

TORONTO, July 1, 1919.

Medical and Public Health Meetings in Toronto.—Three important meetings were held in Toronto during the last week in May. The first of these was the joint session of the 8th Annual Congress, of the Canadian Public Health Association and the 8th Annual Meeting of the Ontario Health Officers' Association, which opened on May 26, and lasted until May 29. The President of the Congress was Dr. J. A. Hutchinson of Westmount, Quebec. The program was a full one and the meetings were well attended.

In the Convocation Hall of Toronto University

on the evening of May 26, the delegates to the Congress, Col. E. L. Keyes, Jr., of the United States army, and Mr. R. Russel of the American Sociological Association, New York, discussed the prevention of venereal disease in the army and in civil life and dwelt largely upon the steps taken to fight the plague. Dr. Russel laid stress on the fact that the closing of the segregated districts in the United States had been done from the standpoint of hygiene and not of morals. The question of morality was not the first consideration but that of public health.

At the afternoon session Dr. J. A. Hutchinson gave the presidential address in the course of which he preferred a plea for a Dominion law which would require the production of a certificate for marriage. Hutchinson said that at the present time there is no law in Canada to prevent the marriage of the unfit person outside the insane asylum providing that a clergyman or magistrate is found willing to perform the ceremony. Such a state of affairs should not be allowed to exist in a civilized and intelligent community. The code permitted clergymen to marry anyone so long as no legal impediment could be found or unless relationship forbade it. He was of the opinion that the public should have the facts concerning the propagation of the feebleminded, and also be informed that the majority of babies born blind came into the world that way through venereal disease, that we must have safeguards in order to produce a healthy virile race. If the sacredness of marriage is believed in, and it is to be presumed that it is, the best way to show the sincerity of the belief is to guard the portals of the marriage state. He held that a law should be passed, because it is impossible for the clergyman to be aware of these facts when performing the ceremony. Such a law would prevent the propagation of the feebleminded and diseased. He thought that alcoholism, tuberculosis, insanity, criminal tendencies, and venereal diseases should constitute a bar to marriage under the law. He drew attention to the fact that several other countries had a law of this kind under consideration.

At the same session a symposium on influenza took place. The majority of those who discussed the matter expressed the views that quarantine was the most effective method for combating the spread of the disease. However, Lieut. Col. McCullough, head of the Ontario Board of Health, dissented from these opinions. His experience had taught him that as soon as the quarantine was lifted the disease was rapidly disseminated. He also was averse to the closing of churches, theaters, and schools, because, if in a city, people mingled in other places. The closing of schools might produce good effects in country places. He pointed out that the theaters and schools did not close in New York, where the cases were fewer in proportion than in a great many other cities. While he knew of many methods taken to control the disease, none really controlled it. The only recommendation he could make to the person suffering from influenza was to get to bed as quickly as possible.

At the evening session Col. Thomas W. Salmon, Medical Director U. S. National Committee for Mental Hygiene, spoke to the delegates on the subject of "Psychiatric Lessons from the War." The address dealt with the treatment of mental and shell shock cases in the army and also in peace time. Col. Salmon suggested that each general hospital should establish a ward for the treatment of mental diseases instead of bringing them to the insane asylums via the police court. He referred to the work of the American army in this direction adding that their method of treatment was also the method adopted by the British and French during the final year of the war. By having experts near the front line they had been able to treat successfully and send back into the line about 6,000 men who in previous years, had been allowed to pass through with the result that their condition became incurable and they were lost to the forces. In this respect all armies suffered heavily during the first part of the war. Col. Salmon expressed the opinion that no disease was so poorly handled or less understood than mental disease. A great number of divorce cases were caused by neuroses. The number of cases in peace time was amazing and yet no steps were being taken to handle them. He thought that such cases should be taken up first in the schools, where there was every chance of effecting a cure. Parents should be so informed that they could recognize the first symptoms.

Dr. C. J. C. O. Hastings, Medical Officer of Health for Toronto gave an address on "State Health Insurance." He favored some such scheme for Canada as was now in existence in Great Britain. He outlined a scheme whereby the workers would pay 50 cents a week, which would enable them to draw a sick benefit of $7 a week, $100 going to their heirs in case of death.

At the session of the morning of May 27, Dr. Adam H. Wright of Toronto, paid a tribute to the memory of Hon. W. J. Hanna the late well known Ontario statesman. Dr. Wright commented on Mr. Hanna's deep interest in prison reform, public health and hospitals.

Dr. Gordon Gallie discussed the question of still birth and gave some interesting statistics on the subject. He pointed out that ignorance and poverty were the contributing factors which were most largely to be blamed. He advocated closer prenatal supervision by medical men and said that the one disease which caused 85 per cent. of the still births was preventable.

Dr. Mary Sherwood of Baltimore dealt with child welfare. She said that 40 per cent. of the drafted men for the American army were rejected because of diseases contracted in childhood, which were preventable. Surgical attention should be given to every mother at childbirth. She also found that the wages of the father had a good deal to do with the health of the child. Because Sweden had established training in the problems of childbirth its death rate from this cause was the lowest in the world. She suggested that instruction should be given in the schools on the subject, and that the State should establish medical research centers.

Dr. Heber C. Jamieson of Edmonton, gave the congress the result of his experiences in child

welfare in Alberta. He said that Alberta had considerably more trouble with the 33.6 per cent. of foreign born children than with the remaining 66.4 per cent. of British born, owing to the foreigners holding to their traditions and refusing to adopt the up-to-date methods in vogue in Alberta. He showed that Alberta had made great strides in child welfare and declared that practically every reform put through in the province could be credited to the votes of the women. In order to aid in securing urgently needed nurses the University of Alberta had waived the matriculation rule for them when they entered to study social service.

Miss K. Olmstead, Extension Secretary of the National Association of Public Health Nursing, Chicago, told of the birth and growth of the movement to provide community nurses in the United States. Wisconsin, she said, had already passed a law making it compulsory for municipalities to have these nurses on the staff. They were now working for a national health department which would make the movement officially recognized.

In the Section of Mental Hygiene of which Lieut. Col. C. K. Russel of Montreal, was chairman, Dr. C. K. Clarke of Toronto, Medical Director of the Canadian National Committee for Mental Hygiene, made an eloquent plea for the better and more careful treatment of the insane and those suffering from mental diseases.

The officers of the Canadian Public Health Association elected for the coming year were as follows: *Honorary President*, Lt.-Governor L. J. Brett, Edmonton; *President*, Dr. H. G. Young, Victoria; *Vice-Presidents*, Drs. J. A. Amyot, Toronto; W. E. Roberts, St. John, N. B.; Colin Campbell, Montreal; *Secretary*, Dr. R. D. Defries, Toronto; *Treasurer*, Dr. F. A. Adams, Toronto.

The new officers of the Canadian National Committee for Mental Hygiene are: *President*, Lt.-Col. Charles F. Martin, M.D., Montreal; *Vice-Presidents*, Rt. Hon. Lord Shaughnessy, K.C.V.O.; Sir Vincent Meredith, Bart., Sir Lomer Gouin, Sir Robert Falconer; *Treasurer*, Sir George Burn, Ottawa.

8. Intestinal Parasites. — I. Valentine Levi draws attention to the reflex causation of disease and the possibility of the presence of intestinal parasites, as, for instance, the tenia, in long continued cases of gastric ulcer, or hyperacidity, that do not permanently respond to treatment. He points out that, as one noted clinician has remarked, the chief characteristic of the clinical picture, in cases due to the presence of intestinal parasites, is its lack of anything characteristic. But though a person may harbor a worm and be unaware of the fact, the tape worm may result in severe symptoms, injury in such cases being attributed in particular to mechanical obstruction, injury or irritation of the intestinal mucosa, loss of blood, loss of food that goes to the parasite rather than to the host, toxines produced by the parasite or by the disintegration of the parasite, such as segments of the tape worm. The appetite varies, it may increase or decrease or be irregular; eructation, nausea, vomiting, abdominal pains, either like gastralgia or colicky (Seeger reports abdominal pains in 42 per cent. of his cases of tape worm); digestive trouble; constipation (Hirsh found it in 5 per cent. of his cases); diarrhea (6 per cent.), or irregularity of the bowels (3 per cent.). Anemia seldom occurs in patients with *Tenia saginata* or *soleum*. Inequality of the pupils and disorders of vision are common, also tinnitus aurium and disorders of hearing. Hirsh reports headaches in 14 per cent. of his cases. Itching and drying of the nose and epistaxis are common; general vague pains in all parts of the body, emaciation when the infection is of long standing, loss of strength, disturbed sleep and any symptoms that may be produced reflexly even to those of meningitis, may occur. In fact, there are few symptoms that have not been present in one or more cases. To illustrate this, the author gives some clinical histories, including his own case, for after three years of suffering from symptoms diagnosed as nervous indigestion, gastric or duodenal ulcer, diverticulitis of the descending colon and intestinal stasis, and on the eve of operation, he passed a segment of a tenia and two days afterward got rid of thirty-three feet of worm with the head, whereupon he had immediate relief from all symptoms. His own experience suggested a similar diagnosis in other cases which proved to be due to the same cause. He states that he has been unable to find any similar case in the literature or in the textbooks and remarks that though there are pages and pages in the textbooks devoted to gastric ulcer and hyperacidity, no reference is made to the tenia in their differential diagnosis.

1. Relation of Internists to Military Medicine.—Walter L. Bierring. (See MEDICAL RECORD, June 21, 1919, p. 1073.)

4. A Method for the Preparation of Prophylactic and Autogenous Lipovaccines.—E. C. Rosenow and A. E Osterberg state that they have tried various procedures in order to simplify the methods used for the preparation of lipovaccines. The chief difficulty encountered has been the fact that the bacteria must be dried, and all methods used for drying have produced a clumping of the bacteria which has necessitated a subsequent grinding process, which was cumbersome, time-consuming and otherwise objectionable. It occurred to the authors, however, that if the water were removed by distillation in vacuo from a water-bacterial-oil emulsion, the oil would prevent the clumping of the bacteria and render unnecessary the grinding process. With this as the underlying principle, they have succeeded in developing a method which gives perfectly even, homogeneous suspensions with various species of bacteria. Large quantities of the mixed vaccine used for prophylactic inoculation against influenza, containing type pneumococci, Group IV pneumococci, green-producing streptococci, hemolytic streptococci and staphylococci, have been prepared by mixing in the centrifugal bowl (as described), the bacteria grown separately, as well as by mixing the dried oil suspensions of the different strains. In addition excellent lipovaccines have been made of typhoid-paratyphoid and dysentery bacilli, of influenza bacilli, colon bacilli, *Streptococcus viridans*

from endocarditis, gonnococci and meningococci. As high as 90 billions of bacteria have been given to a few persons with only slight constitutional and local reactions. A dose of 0.5 c.c. containing 25 billions of the dried bacteria in the oil given to more than 500 persons during a recrudescence of influenza rarely produced more than a slight reaction. However, after the use of this vaccine an occasional person reacted more severely and a sterile abscess formed. Antibody production—agglutinins—was pronounced, which shows that the somewhat prolonged heating in the oil in vacuo does not destroy the antigenic properties. The authors point out that it is imperative that there should be no living bacteria in the water suspension at the time the oil is added. It was thought that the heating would serve the double purpose of killing the bacteria and driving off the water, but this was found not to be so. Suspensions showed living streptococci and other bacteria after prolonged heating at from 60 to 75 C., and temperatures as high as 100 C. for a period of two hours failed to kill after the water had been removed. The heat used in the distillation does not alter materially the antigenic properties of the bacteria and there is good reason to believe that heating the water-bacterial-oil emulsion to the boiling point of water under atmospheric pressure will not destroy the antigenic properties of bacteria, and if this proved to be so, the method may be simplified still further. The authors also point out that in order to decrease the toxicity of the vaccine it is desirable that the distillation be continued until the suspension has become cleared. The clearing that occurs as the oil permeates the dried bacteria is so striking as to suggest actual solution; this, however, is not the case, since on making a watery suspension from the oil the bacteria stain normally and are of sharp outline. It has been found that the oil will not permeate bacteria dried in air as completely as those dried in vacuo in the presence of oil, and experiments carried out by the authors would seem to show that the toxicity of the former should be proportionately greater. They suggest that desensitization against pollen or other protein substances may be greatly enhanced by the use of an oil instead of a saline suspension. The authors are now engaged in studying the value of autogenous lipovaccines in the treatment of various diseases. Striking cures have followed the administration of a single dose of 80 billions of staphylococci in severe recurring furunculosis. Benefit has also followed the administration of autogenous pneumococcus and staphylococcus lipovaccines in infections of the maxillary sinus. Judging from the slight constitutional reactions, even when huge doses have been given, and the improvement in the few cases studied, the authors believe that much good might come from the use of autogenous lipovaccines, especially in the treatment of chronic or recurring infections, when a prolonged immunization is indicated. Lipovaccines should also be of benefit in focal infections, particularly if foci are removed and the specific microorganisms isolated from the focus is contained in the vaccine.

6. Results of Bone Grafting Operations in the Treatment of Ununited Fractures of the Mandible.—W. Maxwell Munby and A. D. E. Shefford draw attention to the desirability of publishing as many results as possible of bone-grafting operations in the treatment of ununited fractures of the mandible, so that some more definite conclusions may be reached as to the success likely to be attained, especially in view of the fact that repatriated prisoners of war and pensioners suffering from this disability are frequently admitted to centers dealing with jaw injuries. From their own series of cases they conclude: (1) Bone-grafting operations give the best results when there are teeth in both fragments, which can then be completely controlled by a splint. In nine cases of such a nature, all, with the exception of our earliest one, were united at the end of ten months, giving 89 per cent. of complete successes. (2) In those cases where there is an absence of teeth in the posterior fragment the operation is only indicated when the pseudoarthrosis is very lax, and marked improvement can be obtained, even if union of the graft is imperfect. Where there is already firm fibrous union causing little or no disability, the operation is not indicated. There were eight such cases in this series; in two bony union was obtained; three were considerably improved, one slightly improved, and two remained in statu quo. (3) Better results are obtained by the use of pedicled grafts than by free grafts in that the former considerably shorten the period between the actual operation and the establishment of union. In this series, when teeth were present in both fragments, union was obtained in all but one case on the removal of the splints, three months after operation when the pedicled graft was used. Where there are no teeth in the posterior fragment the best results are also obtained by use of the pedicled graft. In one case bony union was obtained, and in the second there is considerable improvement, which may ultimately result in bony union. (4) Certain cases where there is a large gap between the fragments are not suitable for a pedicle graft, especially when both ends of the fragments are pointed. In such instances a free graft is preferable. In free grafts the best results are obtained when the graft can be wedged into position and the periosteum stitched with fine catgut. (5) Absence of wound infection is an essential in order to secure satisfactory results. In three successive cases in this series, where kangaroo tendon was used for fixing the graft, some infection of the wound occurred, and although its degree was not severe and the graft was in no case extruded, yet in two instances no improvement resulted, and only to a slight degree in the third. Radiographic examination showed that these grafts were slowly becoming absorbed. (6) The amount of scar tissue present in the area of operation does not appear to influence the result, except that a slight sloughing of the skin flap may occur when it is abundant. (7) Radiographs in fractures at the angle region of the mandible are deceptive, inasmuch as they do not show the true extent of the size of the gap, which is frequently greater than it would appear owing to the fact that the posterior fragment generally become displaced inward and lies at a deeper plane than the anterior.

1. The Oliver-Sharpey Lectures on the Feeding of Nations. A Study in Applied Physiology.—E. H. Starling remarks that although man's first care has always been to provide his daily bread, the science of dietetics is of comparatively recent origin, and it was not until the great war broke out that any of the nations awoke

to the fact that efforts to provision a community would be disastrous unless based upon physiological principles. At the very beginning of the war the Royal Society founded a physiological war committee to make recommendations to the Government on any question involving physiological principles, and in 1915 a subcommittee was entrusted with the examination of all questions affecting food. This subcommittee first undertook an examination of the probable position in enemy countries, and concluded that a predominant factor of the German economic position was likely to be a shortage of available fats and oils, pointing out the necessity of the most stringent limitation of imports of fat into Germany. Since the armistice we have learned how true these predictions were and how much the duration of the war might have been curtailed had the importance of real restriction of importation of foodstuffs into Germany been recognized. The subcommittee then estimated the food supply of the United Kingdom and compared this with the requirements of its inhabitants. They suggested as means of economy a higher recovery of flour in milling, less meat production, increase in the manufacture of cheese at the expense of butter, use for food of materials employed in brewing and distilling, and the diversion of certain quantities of material used for stock feeding to human use. All but one of these recommendations were ultimately adopted, and from the time of Lord Rhondda's appointment as Food Controller in June, 1917, the Royal Society Committee acted practically as a scientific consultative committee in all matters of food supply. Toward the end of 1917, wher it was decided to pool the resources of the allied countries, it became necessary to create an international scientific organ and in March, 1918, the Inter-Allied Scientific Food Commission was appointed. As a result of the measures taken, the average consumption per head in the United Kingdom remained almost stationary during the war and little below that of peace time. The estimate before the war was 3,410 calories per man; for 1916-17 it was 3,357 and for 1917-18 it was 3,377. As evidence of the effect of a restricted food supply, the author mentions the prevalence of tuberculosis in Germany in the later years of the war. Turning to the provision of food, he points out the wastefulness of animals as energy converters from the point of view of the human consumer, but that necessity for providing fat is the real physiological justification for the use of animals for human food. The Germans made the serious mistake of permitting the maintenance of large stocks of horned cattle, with the result that large quantities of food were wasted without any production of meat or fat; the ill-fed cattle deteriorated, their working powers diminished, the milk supply became less and less, and there was a fat famine throughout the land. Passing to the question of rationing, the author points out that the key of the problem is the provision of sufficient calories by diversion of food from animals to man, and the assurance of equitable distribution. If all foods are rationed, however, equitable distribution must fail, as the same quantity is not sufficient for each individual. It was because of this fact that it was decided that bread must remain unrationed at all costs, but it was made sufficiently unattractive to prevent wastefulness. The maintenance of free purchase of bread demanded a strict adjustment of the importation program, and the Royal Society Committee assigned the following order of preference: A sufficient amount of cereals should be imported as breadstuffs to avoid rationing and to serve as an elastic reserve for the energy needs of the country, and all cereals in the country should be reserved as breadstuffs to meet the full demand for these. A minimum of 16 ounces of fat should be provided a head a week, taking into account not only the meat fat and margarine, but also the fat contained in milk, wheat, and other foods available. In order to bring up the fat of the food to this amount the necessary quantity of bacon, fat, meat, and oil seeds must be imported, and the home supplies conserved by limiting the use of fat for industrial purposes. A minimum supply of sugar amounting to 8 ounces a head a week must be supplied. Up to these figures, which were regarded as minimal, the import of food should take preference of all claims on shipping. Any tonnage then available for supplying the country with food should be utilized to bring the meat ration up to 2 pounds a head a week. The author adds that the United Kingdom was the only nation in Europe in which no man, woman or child had to go hungry or leave hunger unsatisfied on account of war conditions.

April 14, 1919.

Pyramidon in Febrile Infectious Processes.—J. Schürer has verified the remarkable sedative action of pyramidon in restlessness, hallucinations, and motor agitation in infectious diseases. Delirium and prostration are likewise relieved by the drug. This symptomatic action is in no way dependent upon an antithermic action and takes place without any drop in the temperature. Similar results were noted in cases of typhoid fever. To explain these results, the writer invokes Weber's researches, which seem to show that pyramidon exercises a depressive action on the tension of the cerebrospinal fluid. Therefore, the drug acts in the same manner as lumbar puncture. Its exhibition is frequently indicated in typhus fever, and less so in typhoid; in the latter the drug may cause collapsus. The writer believes that it may be possible to obtain a decrease of the death rate of typhus with pyramidon, and his own experience, although small, seems to bear out his hope.

Hirschsprung's Disease Simulating Ileus.—Brandenstein reports the case of a patient who had never been ill nor constipated. The onset of the affection was in the form of an acute intestinal catarrh when the patient was thirty-nine years old. After a few days of diarrhea a large transversal cord-shaped tumor could be felt in the abdomen, and a diagnosis of occlusion of the descending colon was made. At operation the colon was found generally dilated; the sigmoid flexure was almost absent; the descending colon was perfectly straight down to the anus; incision of the colon and evacuation of a large quantity of fetid matter. The walls of the large intestine were one centimeter thick. Recovery.

The Physiology of Alimentation During the War.—A. Loewy and H. Strauss offer a second contribution to this subject and divide the evolution of inanition into three clinical phases. In the first phase there is loss of weight without any evident disturbances and no morbid symptoms are noted. On the contrary, certain persons are improved physically by the diet imposed by the war, such as plethoric individuals and diabetic and gouty patients. The size of the fetus does not appear to have been influenced by the reduction of maternal feeding—a fact which demonstrates the uselessness of the so-called Prochovnik's treatment where the mother is put on a diet intended to keep down the weight of the fetus in order to render labor less difficult. The second phase consists of a loss of weight with mild pathologic symptoms. The nervous system is more apparently involved, the symptoms offered being irritability, intellectual and physical paresis, etc. The subject is more sensitive to infections, particularly tuberculosis, dysentery, and influenza. In the more advanced phase severe symptoms arise and place the patient's life in danger, namely the development of edema disease. Those who have suffered the most from inanition are subjects with digestive affections, such as gastric and duodenal ulcer, as well as connected syndromes, likewise cases of cholelithiasis. The writers also refer to intoxications from mushrooms and trichina, which are to be put on the account of war diet, etc.

The Epidemiology of Tuberculosis.—L. Teleky offers a critical and statistical study relating to various factors which may modify the general percentage of tuberculosis. The gravity of infantile tuberculosis depends upon internal and constitutional causes, in opposition to social factors. The same applies to tuberculosis of puberty. The diminution of the general mortality of tuberculosis, which pre-war statistics showed, is carefully considered by the writer, who rejects the rather general present opinion which maintains that it is the frequency of early infections which diminish the gravity of the evolution of the disease in adults. In oppo-

sition to this theory, the writer invokes, for explaining the regression of the disease, a general amelioration of the conditions of the working classes, social hygiene, etc.

The Various Forms of Headache of Nasal Origin.—L. Stein distinguishes six forms, namely: (1) Pain resulting from retention of the secretions in a sinus; (2) pain from occlusion of a sinus, resulting in absorption of the air, with a consequent negative pressure; (3) pain from pressure on the septum; (4) pain from distention of the mucosa of the conchæ and elongation of the nerves; (5) from obstruction to the flow of the lymphatics from the brain, and (6) reflex headache.

Correspondenz-Blatt für Schweizer Aerzte.

March 29, 1919.

Manifest and Latent Pleural Empyema.—Schweizer refers to the high mortality of empyema which is responsible for the heroic treatment of this condition by rib resection. Empyema is due to the most numerous and varied conditions which fact naturally has considerable bearing on the treatment. The operation mortality varies from 5 to 40 per cent. in these acute and subacute states. There are also several types of chronic empyema which must be considered. One of these represents the residue of an acute attack. The behavior is typical, for the tendency is largely fatal, amyloidosis or cachexia being apparently inevitable. The author would now isolate from the preceding a type of case not lethal in its tendency. There may be a tendency to chronicity with or without effusion into the pleura. The subjects are essentially invalids, but still able to support themselves. They may be laid up for short spells but this is the exception. These cases are manifest, not latent. In very rare cases we see true latent empyema. In all of these types extreme chonicity is possible. Contrasting these three types victims of the first probably know the nature of their condition because they have been operated on at some time; those of the second class know themselves to be invalids, but have up to the time of operation no special insight into their condition, some of them being tuberculous. In the third type the patients feel perfectly well. In many unoperated cases the condition comes to light only at the autopsy.

Mortality and Results of Nephrectomy.—Thellung having analyzed a rather small number of nephrectomies finds a primary operative mortality of 11 per cent. and a remote mortality of 6 per cent. Otherwise stated over 80 per cent. of survivorship was obtained and of these the majority were able to earn their livings. The further outlook is modified by the nature of the disease, but of the unilateral renal tuberculosis at least one-half should be permanently cured by nephrectomy.

Journal de médecine de Bordeaux.

April 25, 1919.

Indemnity for Hysteria.—Cruchet considers this subject from its military aspect, although, doubtless, the latter does not differ essentially from the industrial aspect. The question of indemnity is excellent to bring out the distinction between actual disease and simulation. Charcot was the first to demonstrate that hysteria was a true disease, corresponding in some degree to possession, and quite distinct from simulation. But with the advance of psychoneurology it was seen that distinction was often impossible and finally Babinski decided against making any distinction in practice. The term hysteria, according to him, should be reserved for the actual manifestations commonly known by that name, such as contractures, paralyses, anesthesias, and various forms of seizures. Simulation is a word of considerable range and is not necessary to consider the motivation, whether unconscious or conscious. Cruchet makes a distinction between unconscious simulation (such as imitation), perseveration, exaggeration, and that which we have termed hysterica proper. In theory, and generally in fact, these subjects recover with or without treatment. But if the question of indemnity is involved there is no choice—they must be classed as sick or disabled. The damage suffered by the individual after injury must be expertized. To take a concrete example, a purely functional paralysis of the hand. There are rules for unmasking the simple simulator, but is is more difficult to isolate exaggeration and perseveration, for these are what count in fixing the disability. If we can eliminate all three factors we can reckon the subject as truly impotent. In such a case the mechanism may be various—simple suggestion, imitation, mental contagion, obsessions and fixed ideas, to which may be added aboulia, asthenia and other mental components often difficult to expose. The patient must be treated before the compensation is fixed. An old custom has been to idemnify these patients exactly as in the case of the same disability, due to organic disease after the diagnosis has been arrived at, of essential hysteria. This procedure requires checking up with others, one being an estimation of the mental state.

Revue médicale de la Suisse Romande.

April, 1919.

Grippe Delirium.—Schlesinger calls attention to the association of delirious states with the febrile phase of influenza, but the delirium is not merely a function of the fever for it has appeared both before and after the latter, is not variable in proportion to the intensity of the fever and does not run concurrently with the latter. It may be ordinary subacute or typhoid delirium. Insight cuts no figure in prognosis, for in subjects with perfectly lucid periods death may not be far off, and the converse is true. It is admitted that a rise of temperature in the midst of a delirious case may aggravate the delirium or cause a lucid mind to become clouded but, as abundantly stated, there is no necessary connection between the two. In subacute delirium the patient may be seized suddenly with motor activity and may perhaps even leave his bed and cell, running against hard objects, becoming covered with blood and feces, and in some cases heading directly for an open window. Strange to relate, these men may retain considerable insight as to their condition with good orientation and state that they are merely swayed by an irresistible power. The behavior is like a fugue on a small scale. It is evident that many of these sufferers are badly frightened, they know not at what. Such cases have been seen in other infections and the author classifies them as infectious deliriums. During convalescence we are apt to see now and then a catatonic state associated with post grippal asthenia. Some of these exhibit peculiar automatisms, as singing or whistling one tune indefinitely. It is impossible to tell in some of these cases whether or not precocious dementia is setting in. It has been necessary to interne some of the patients. A few cases of delirium tremens developed in grippe patients.

Features of the Recent Pandemic.—Gouget lays stress on some phenomena studied at the height of the pandemic. One of these was total absence of any discharge from the nose, along with extreme rarity of any sinus or ear location. By contrast anginas were common. The alleged polymorphism he scouts. All of the cases seen were thoracic, whatever chance affections might have coexisted. Hemorrhages were a feature, some of rare character, as intramuscular hematoma. At autopsy edema of the lungs was never absent. Fibrinous exudate was very slight in degree, and the pneumococcus could be exculpated as a cause. The disease was very severe in those with old lung affections—simple chronic bronchitis, emphysema, thoracic deformity, cardiopathies and tuberculosis in full evolution. It was objected that the author dealt essentially with hospital cases and that his description did not hold good for healthy extrahospital patients. In the latter class the condition was apt to be like a general infection from which even pulmonary lesions might be absent.—*La Presse Médicale.*

Book Reviews.

ADVANCED SUGGESTION (NEUROINDUCTION). By HAYDN BROWN, L.R.C.P., Edin., Fellow of the Royal Society of Medicine. Price $2.50 net. New York: William Wood & Co., 1919.

POSSIBLY only psychiatrists realize how great a part suggestion plays in nearly all therapy; certainly it is the *sine qua non* of all psychotherapy. The psychoanalysts assert that it has no place in their method; their opponents allege that it is all but everything. This little book is an exposition of the most modern ideas on suggestion with detailed descriptions of its use in such varied fields as chorea, dementia precox, color-blindness, seasickness, drug addiction, hemorrhoids, cancer, and eczema. One must not assume, however, that there is any savor of charlatanism in this; the author merely indicates the usefulness of this therapeutic method in combating symptoms and in inculcating a healthier psychic attitude in the patient, whether his malady be physical or psychical or both. The author's psychology and its applications do not lend themselves to abstracting but, however much they will be challenged by other psychologists, they contain much of value. Altogether this is the sort of book the general practitioner should buy, and having bought, should read. It is of such a handy size that it can be slipped into the overcoat pocket for the spare moments that even the physician has now and then.

THE OPERATIVE TREATMENT OF CHRONIC INTESTINAL STASIS. By Sir W. ARBUTHNOT LANE, Bart, C.B., Consulting Surgeon to Guy's Hospital and to the Hospital for Sick Children Great Ormond Street. Fourth Edition, Revised and Enlarged. London and New York: Oxford University Press, American Branch, 1918.

WITH the exception of a new preface of about five pages written by Lane, this book is a reprint of the third edition (reviewed in the MEDICAL RECORD October 9, 1918), plus 127 pages of new material contributed by nine other authors. In the new preface Lane describes the genesis of the various adventitious bands and membranes which he says at first support and later interfere with the function of the intestine, the best known of which are the so-called Jackson's membrane, which extends from the abdominal wall to the outer wall of the caecum, and a band originally developed on the mesentery of the ileum and sometimes ultimately causing a kink of the ileum near its junction with the caecum—the so-called Lane's kink. The development of bands and thickenings in the duodenopyloric region is also taken up and the possible disastrous results such as gastric and duodenal ulcer, biliary and pancreatic lesions, are pointed out.

As a consequence of intestinal stasis and intragastrointestinal infection of the food supply, Lane says that the circulation is flooded with toxins or organisms in excess of what can be dealt with by the liver, skin, and kidneys; and he finds that colectomy in patients with Still's disease, rheumatoid arthritis, and Raynaud's disease gives wonderful results within twenty-four hours. With some other observations, mention of which is precluded by lack of space, Lane says: "The above form the outlines of the clinical picture which will develop in the following chapters. Some of the conclusions will be found to be plain and obvious, while others are by no means so easily understood."

The new chapters shed considerably more light on the subject. The titles and authors of these chapters are: "The Great Bowel; from the Anatomist's Point of View," by Arthur Keith, M.D., F.R.S.; "On Intestinal Stasis Intoxication and Subinfection," by J. G. Adami, M.D., F.R.S.; "The Blood Pressure in Intestinal Stasis," by Major A. White Robertson, R.A.M.C.; "Intestinal Toxemia and Loss of Accommodative Power," by Ernest Clarke, F.R.C.S.; "The Medical Aspect of Intestinal Stasis," by Leonard Williams, M.D.; "Chronic Streptococcic Infection of the Alimentary Tract," by Nathan Mutch, M.D.; "The Investigation of Chronic Intestinal Stasis by the X-Rays," by Alfred C. Jordan, M.D., M.R.C.P.; "The Gynecological Aspect of Chronic Intestinal Stasis," by Harold Chapple, M.C. (Cantab.), F.R.C.S. (Eng.); and "Pyorrhœa and Its Relation to Chronic Intestinal Stasis," by Harry Forsyth, L.D.S.

While it is almost certain that few will agree *in toto* with what Lane and his co-authors have to say, the book is interesting and well worth reading by all practising physicians and surgeons, whether they advocate or deprecate the operative side of the question.

DISEASES OF THE SKIN. By JAMES H. SEQUEIRA, M.D., Lond., P.R.C.P. Lond., P.R.C.S. Eng. Physician to the Skin Department and Lecturer on Dermatology at the London Hospital; in charge of Queen Alexandra's Department for Light Treatment; Honorary Consultant for Diseases of the Skin to Military Hospitals in London; Consulting Dermatologist to the Radium Institute; Secretary of the British Section of the International Association of Dermatology and Syphilology; Fellow (late Secretary of Dermatological Section) of the Royal Society of Medicine; formerly Physician to the North Eastern (now Queen's) Hospital for Children Third Edition. With 52 plates in color and 257 text figures. Price $12.00. Philadelphia: P. Blakiston's Son & Co. 1919.

This is one of the most complete works on the skin now published. Moreover, as in the first instance it was an elaboration of notes set down for a course of lectures to the students of the skin clinic of the London hospital, it is of an eminently practical character. The skin clinic at the London hospital has won a well deserved reputation for three reasons because it has an abundance of material and because of the fame of Dr. Sequeira and because of the excellence of its equipment. The second edition was exhausted soon after publication, and on account of the war the appearance of this, the third edition, was considerably delayed. However, the war has afforded opportunities for research with relation to skin affections of parasitic origin and for the study of venereal diseases. These opportunities have been employed to great advantage and the results have been embodied in this book. The present edition has been most carefully revised, parts have been rewritten and in all respects it has been brought up to date. The illustrations are good and as a text-book of skin it may be strongly recommended.

THE BLIND, THEIR CONDITION AND THE WORK BEING DONE FOR THEM IN THE UNITED STATES. By HARRY BEST, Ph.D. Author of "The Deaf": Their Position in Society and the Provision for Their Education in the United States. Price $4.00. New York: The Macmillan Company, 1919.

ON account of the injuries to eyesight caused by the war greater interest is taken in the subject of blindness and better methods of dealing with those afflicted have been evolved, than ever before. Dr. Best's book discusses blindness from all standpoints and particularly with reference to blindness in America. He believes that although the lot of the blind in this country has been greatly improved, that we have still a long way to go. He points out that an obstacle to the interest of the public in the fate of the blind is the fact of the comparative ignorance which exists as to their real problems and needs. A study of Dr. Best's book will dispel this ignorance.

RATIONAL THERAPY. By OTTO LERCH, Ph.D. M.D. Professor of Medical Diagnosis and Treatment, Tulane University of Louisiana. Post Graduate Department. Troy: The Southworth Company, 1919.

THIS work on therapeutics is based on the view that blood alone cures. That is, that in the treatment of all diseases, the object must be to purify the blood. In accordance with this viewpoint the author pays especial attention to the question of diet, as well as to the occupation and to the climate in which he lives. Dr. Lerch lays much emphasis on the influence of rest both in the prevention and treatment of disease. Physical therapy is fully discussed. The entire motive of the book is founded upon the idea that the purification of the blood is the sole successful method for treating disease of any description. The manner in which disease is dealt with is original and the arrangement of the book is different from the usual work of this kind. Dr. Lerch wishes to emphasize the point that the book is not a compilation but embodies the experience gained in practice and teaching.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Seventieth Annual Session Held at Atlantic City, N. J., June 9, 10, 11, 12, and 13, 1919.

(Special Report to the MEDICAL RECORD.)

(*Continued from page* 88.)

SECTION ON SURGERY.

First Day—Wednesday, June 11.

The Probable Influence of War Surgery on Civilian Life.—Dr. JOHN T. BOTTOMLEY of Boston, chairman of the Section, delivered this address. He said that no entirely new principles in surgery were established during the war, some of the known principles, however, were emphasized and strengthened. For a while it looked as though the problems were of such magnitude as to overwhelm those who were to solve them, but the medical profession demonstrated that they were equal to the task. He called special attention to two measures in surgery brought to the front as a result of the war, the practice of débridement with closure of the wound by primary suture and the Carrel-Dakin method. Testimony of many men whose judgment could be relied upon showed the value of the above methods. Many objections which were present during the war in carrying out the Carrel-Dakin method of treatment were not valid in civilian life when conditions for any surgical treatment were more favorable. In the opinion of the speaker the practice of "débridement" would exercise a great influence on the practice of surgery, the principle would be applied in civilian life in treating injuries sustained in the larger industrial plants, and through it he hoped many a limb and many lives would be saved. The war emphasized the importance of prompt antiseptic treatment, and the mechanical cleansing of wounds was more important than the chemical cleansing and sterilization. In the opinion of the speaker the success of surgery during the war was due in part at least to the good hospital organization and good team work among the various workers, the activities of the chemist, pathologist, bacteriologist, surgeon, and all the others were centered on the patient, the splendid results obtained in plastic surgery were the result of cooperation between the dentist and surgeon; war experiences had also shown that chest operations were much less dangerous than was supposed and that the lung tissue could be extirpated without the aid of complicated air compression appliances. In conclusion the speaker sounded a warning to the young men who did some surgery during the war not to consider themselves full-fledged surgeons when they returned to civilian life; he hoped the experiences in that respect which followed the Civil War would not be repeated.

Traumatic or Wound Shock.—Dr. WALTER B. CANNON of Boston read this paper. He defined shock as a general bodily state characterized by a low blood pressure, rapid heart action, accelerated breathing, sweating, low temperature, and mental dullness. The picture in severe wounds was quite frequently complicated by infection and hemorrhage, so that it was difficult to analyze "pure" cases of shock in humans. He emphasized three points: (1) If shock was reproduced experimentally it was of fundamental importance to reproduce it under the exact conditions under which shock occurred in humans; in his experiments the muscles of the thigh of cats and dogs were severely injured by hammering or crushing the parts without even breaking the skin; for about fifteen minutes no change was observed, then the blood pressure began to go down until the animal died or the experiment ended. (2) Cutting out the nerve of the thigh and reproducing the same experiment resulted in the same lowering of blood pressure. (3) If blood vessels were tied and the same experiment was reproduced, the resulting condition was the same as given above. The vessels were left tied for 35 minutes and no change resulted, but when untied the blood pressure would begin to go down, while if tied again the pressure would begin to rise; local loss of fluid was not responsible for the shock and resulting low blood pressure, as when there was a breaking of the femur the blood pressure was still lower, which by the way emphasized the importance of keeping bones immobilized. His observations led him to believe that shock was not due to injury of the nerve, but that the lowered blood pressure was due to something given off by the injured tissues of the body; the secondary effect upon the body of the low blood pressure was deficient oxygenation resulting in the production of lactic acid and giving rise to the condition known as acidosis. He concluded by saying that wound shock was due to the passage of toxic material from the injured tissue to the other parts of the body, that if the blood pressure went down to the critical level of 70 mm. irreparable damage was done. The moral was prompt treatment and prevention of toxins entering the circulation.

Hemorrhage and Transfusion.—Dr. BERTRAM M. BERNHEIM of Baltimore read this paper. He said that experiences in France demonstrated in a decisive way that nothing could take the place of blood when hemorrhage had reached a certain point. The former teaching that a patient rarely died from hemorrhage was fallacious. Saline solution, though having a limited field of usefulness, was of value and he deplored the fact that the exigency of war did not permit more study to obviate some of the deficiencies of the saline method. In some cases, in which 500 to 1000 c.c. of saline solution had been given, improvement was noted, but when operation was performed death resulted; while in the same type of cases when blood had been given recovery was the result.

Dr. GEORGE W. CRILE of Cleveland said that he approved of all that Dr. Bernheim said with reference to blood transfusion, but as to shock he wished to call attention to the fact that the physiologists of Great Britain had not as yet come to one conclusion on the subject. He thought it would be unfortunate to accept Dr. Cannon's point that the absorption of toxins from the injured tissues was the only cause of shock. Shock occurred in cases where the tourniquets had been used and there was no question of toxins having passed into the circulation. He was afraid that if it became accepted that the nerves had nothing to do with shock surgeons would become rough and careless in handling tissues.

Dr. OSWALD H. ROBERTSON of New York said that while it was generally agreed that in severe hemorrhage blood was of great use, gum acacia injections should not be discarded. There were four classes of cases where gum acacia injections were of no avail, (1) where shock and hemorrhage had existed for a period of 24 hours, (2) where no stimulants were used, but the injections had been given at once; (3) where there had been great loss of blood; (4) where there had been concealed gas infection.

Dr. HOWARD T. KARSNER of Cleveland said that while he supported Dr. Bernheim's views regarding blood transfusion he questioned whether the sodium citrate method as advocated was the best one. He was impressed by a paper of Lindeman, who had described transfusion through a needle syringe. The more immediately the blood was transferred from donor to recipient, the better it was.

Dr. LEWISOHN of New York said that he was very gratified that the sodium citrate method which he had first suggested in 1915 had been accepted by the American Expeditionary Forces. The dose of sodium citrate used was so small that it could not produce any toxicity, and while it lengthened the coagulation time of blood in the test tube, in the human being that was only temporary; the advantages of the method were its simplicity, flexibility, the fact that the patient and donor did not have to be attached, and that the operation could be repeated as frequently as it was desired. The disadvantages of the method were the occurrence of chills, but with proper attention the percentage of chills occurring could be greatly reduced.

Dr. CANNON in closing, stated that he was fortunate to have seen the latest reports of the British physiologists on the subject and there was complete agreement; he had presented his communication before the Societé de Biologie of France and it was accepted. The shock that Dr. Crile saw as a result of nerve injury he thought was only secondarily due to nerve injury. He agreed with Dr. Crile that great gentleness during

surgical operation was necessary, not because of possible injury to nerves, but because of injury to soft tissues.

Dr. BERNHEIM, in closing, said that if to the nerve injury of Dr. Crile and tissue injury of Dr. Cannon a little blood was added, the problem of shock could be solved. He thought that the claims of Dr. Robertson for gum acacia were out of place, for it never did any good and in many cases actual harm resulted.

"Débridement."—Dr. DEAN D. LEWIS of Chicago read this paper. He said that perforating wounds caused by bullets should be treated in the old conservative methods; in wounds caused by explosive bullets, by shell fragments and gutter wounds where muscle tissue was exposed, "débridement" should be used, and devitalized tissue should be removed until muscle that bled freely and contracted was reached.

Primary and Secondary Sutures.—Dr. EUGENE H. POOL of New York read this paper. He said that it was important to remember that military surgery was being performed under two conditions, that of comparative quiet and during periods of great activity. Early closure of wounds could be done only during quiet periods when the patient could be watched and studied. The advantages of the method were limitation and prevention of infection; the disadvantages were the possibility of including in an imperfectly excised wound pyogenic microorganisms. The results of the operation depended to some extent upon the period which had elapsed between receipt of the wound and the operation, the location of the wound, and whether large lacerations of soft parts were present. Where haste was required primary suture should not be done. It was specially indicated in wounds of the face, scalp, and hand. To obtain the best results it was necessary to do a perfect "débridement," control hemorrhage, cleanse the wound with either iodine or ether, approximate deep parts with catgut and superficial ones with silk, immobilize the part, and examine cultures from the wound; if hemolytic cocci were found the wound should be opened at once; primary suturing was possible in 60 to 70 per cent. and in 80 to 90 per cent. the operation was successful; whether a wound was suturable depended upon the bacteriological examination of the presence or absence of hemolytic cocci; the presence of other cocci was no contraindication to primary suture.

Dr. FRED W. BAILEY of St. Louis said the subjects in the papers presented were so fully discussed that little was left to be added; he wished, however, to emphasize the importance of careful surgery in the performance of the "débridement" operation; all devitalized parts must be removed; he thought débridement of bone was much neglected, resulting in many cases which must be cared for in hospitals and which could have been saved by proper "débridement" at the time.

Dr. TURK of New York said that as an assistant to Dr. Murphy he injected peptones from wounds and devitalized tissues and immediate death was the result; death was due to autolyzation of tissue and not to infection. He had begun research along that line in 1897 and for the past 25 years had written several papers on the subject, but evidently the American surgeons failed to utilize his teachings. He insisted that "débridement" was an American work, and did not originate in France or England.

Dr. MACRAE of Council Bluffs said he regretted that advantage had not been taken of "débridement" earlier, since the British and French had been practising it before we entered the war.

Dr. THOMPSON of Chicago said that no amount of paper reading could make any one competent to do a "débridement" intelligently. He thought there were enough competent surgeons in France, but they had not had the opportunity to perform the operation practically.

Dr. SPEED of Chicago said that there was a lack of seasoned surgeons in the army, that he himself and others had done "débridement" before we had entered the war. The trouble however, had been that men who had had actual experience were given subsidiary positions.

Dr. LEWIS, in closing the discussion, said that it was interesting to note that cases where there had been badly devitalized tissue showed little shock; he also wished to emphasize the point that "débridement" could not be taught by lectures or paper, but that it had to be actually done; anatomical surgeons were needed and not physiological ones.

Gas Bacillus Infection.—Dr. FREDERICK T. VON REUBEN, Jr., of New York read this paper. He said that the incidence of gas bacillus infection was reduced from 3 to 1 per cent. and the mortality to half, which was due to a number of factors. In the later period the ground on which the people fought had not been manured and the season was more favorable; rapid transportation and better primary fixation of fractures were, however, the most important factors. Gas bacillus infection could occur in any wound, but was more frequent in large wounds of the lower extremities. He emphasized the importance of operative interference as the only method of treatment for gas bacillus infection. All haste should be avoided. It was necessary to go between the muscles, opening freely and removing all nonbleeding and noncontractile tissues; immobilization of the part was the next important procedure; the Carrel-Dakin treatment was in his opinion the best postoperative method of treating gas bacillus infection.

Sterilization of Wounds.—Dr. GEORGE A. STEWART of Baltimore read this paper. He said that mechanical sterilization of wounds could be accomplished where the case was observed right after injury; primary sutures could then be used. When observed two or three hours later, some form of chemical sterilization had to be used, and when infection had existed for some time more extensive methods had to be resorted to. Wounds of bones and deeper parts presented greater difficulty. For chemical sterilization he proposed the Carrel-Dakin solution which he emphasized had to be of a definite percentage of alkalinity; its preparation required the same care as that given an instrument before it reached the operating table. It had to be fresh and protected from light and it was important to regulate the flow of the solution and to insure the contact of the solution with the entire surface of the wound. By means of chemical sterilization many wounds which had been suppurating for years were successfully closed.

Dr. A. DEPAGE of Belgium said that by sterilization of war wounds was meant the reduction of the number and virulence of the microorganisms to enable one to perform primary suture; it did not mean radical destruction of all microorganisms. Tissues in various parts of the body offered various degrees of resistance to microorganisms, the flora of the wound was important; Dr. Levaditi had demonstrated 14 different microorganisms in wounds; some organisms adapted themselves very easily to conditions of the wound; streptococci did not adapt themselves very easily, but when once established they were hard to get rid of, and suturing of wounds when streptococci were present invariably resulted in failure; staphylococci, however, easily invaded the body, but their presence was no contraindication to primary suture. Bullet wounds gave 40 per cent. infection, shell fragments 80 per cent., and pieces of clothing 100 per cent.

Second Day—Thursday, June 12.

War Problems.—Dr. CHARLES H. MAYO of Rochester, Minn., delivered this address. He said in part that the war had produced a mental quickening, and the medical profession had reason to be proud of the manner in which it had carried out its work. In previous wars disease produced more deaths than the casualties, and in this war the real strategy was not a military one but a medical one, the failures of the Mesopotamian, Crimean, and Boer wars were medical failures. In the war just passed, due to the genius of former Surgeon General Gorgas, disease was reduced to half and the death rate in the army was lower than that in civil life. The speaker deplored the fact that the General Staff had failed to give proper recognition to the medical profession for the work it had done. He advocated higher rank for medical men, which was important because of the authority and responsibility it carried with it. The Government had spent comparatively little in training medical officers. Many had entered the service with years of experience in hospital and civil practice, and their experience should have

been recognized. He called attention to the small number of high ranking officers who were assisting the Surgeon General compared with the number of officers of high rank conducting correspondence in other departments; the war had brought out the fact that 8,000,000 children under 10 years had no education at all and 70,000 soldiers could not read; he hoped that national supervision of education would result and with it national medical supervision would come. He strongly advocated the appointment of a medical secretary as a member of the cabinet. Under existing conditions every branch of the government and many special committees had a hand in medical problems, and these were overlapping each other and failed to cooperate, which condition could only be remedied by centralizing all the medical work in one department under a health secretary. He lauded the work of the National Medical Museum, where much had been accomplished by medical officers, though they had had a ridiculously small sum at their disposal. He hoped that the Walter Reed Hospital in Washington would be made the ideal hospital of the country; the increased cost of maintaining such a hospital would repay with interest in the form of efficiency and care for the sick and wounded.

Peripheral Nerve Injuries.—Dr. CHARLES H. FRAZIER presented this communication. He said there were about five thousand peripheral nerve injuries as a result of the war. The ulnar nerve in the upper and the sciatic and popliteal nerves in the lower extremities were those most frequently injured. One of the most difficult conditions following nerve injuries had been fibrosis of joints, which often resembled rheumatoid conditions. The atrophy which was frequently present was not due to trophic changes, but to disuse of the joint. Regarding the time of operating on peripheral nerves, he thought about three months after healing of the wound was a good time. Splinting of the part was very important. It was necessary to examine sections of the peripheral nerve while the patient was on the table and to keep on resecting until healthy nerve cells appeared in the section. The safety razor had been found the most convenient instrument for resection of nerves. The difficult feature was the bridging of the gap after resection. Transposition of the course of the nerve, placing the limb in certain positions and stretching were some of the methods used. Nerve graft or nerve transplant was the last resource in bridging over gaps and for this purpose any nerve could be used. Stimulation of the nerve with the faradic current while the patient was on the table had been of great help and in many cases it showed that no resection was necessary.

Dr. MARTIN B. TINKER of Ithaca, N. Y., said his observations were based on a series of 300 cases which had been well studied. He agreed with Dr. Frazier that three months after the injury was the safest period for operation. Latent infection was the chief danger. In his opinion nerve graft or autotransplant was more advisable than suturing nerve ends under tension. The subject of peripheral nerve injury deserved serious consideration by all those who were interested in industrial surgery, for many crippled individuals could be saved thereby.

Dr. W. W. BABCOCK of Philadelphia said that his observations were based on a study of 419 cases. The ulnar, musculospiral, and sciatic nerves were the most frequently injured. Neuralysis, splitting of the sheath and suture of the nerve were the operations performed. No harm was ever done by operation and in cases of doubt it was better to operate. In 160 suture cases no nerve grafting or bone resection was necessary; by free separation of the tissues and by placing the limb in certain positions much could be accomplished. In one case he had resected 17 cm. in two operations. There was a question here whether the strain upon the nerve was going to interfere with recovery, but in his experience the results did not differ from the following short resections. He did not wait three months, when there was an open wound, before doing an operation; instead he practised sterilization and operated at once.

Dr. CHARLES BAGLEY, JR., of Baltimore, said that the importance of nerve surgery was demonstrated to him when he had made a tour of inspection in the Canadian hospitals. Most of the work had been done in England, the patients being then sent to Canada. Many cases resulted in fibrosis with terrible deformities. In our army the work of reconstruction was organized early and very few deformities resulted. Nerves should be sutured as soon after injury as possible; in practising "débridement" in bad wounds some nerve tissue had been undoubtedly removed, but in some cases where early suturing had been done the results were quite satisfactory. A case where the popliteal nerve had been completely divided and was sutured at once showed good results.

Dr. ALFRED W. ADSON of Rochester, Minn., said that the subject was timely because one would meet many patients discharged from the service with nerve paralysis. The point the patient was interested in was whether he would recover, and that would depend upon whether a primary suture was used, the length of stretching required, and how long after injury the operation was performed. His experiments on 300 cats and dogs demonstrated to him that a nerve could stand a certain amount of stretching, but not too much. Whenever possible end to end suturing was the ideal method. Where a long gap had to be bridged over tubulization or autogenous transplant was more advisable. It was his rule to be very careful about resection when a nerve retained 50 per cent. of its function. As to how long after injury regeneration could take place, his experiments showed that within the first year the chances were good, within the second year fair, but after five or even three years the chances were practically nil.

Dr. BYRNE of New York said he was interested in the subject because of the work he had done for several years in the Fordham hospital. The outstanding feature of Dr. Frazier's paper was the statement that the division of degrees of sensibility into epicritic and protopathic, as established by Head, had been exploded; his own division was that of afferent sensibility, hurt pain, and critical sense. Some failures of men who studied peripheral nerve injury cases were due to the fact that they had studied the local condition of the nerve only instead of studying the neuron as a whole. The principles of degeneration and regeneration were quite well known and had been worked out before the war, and it was deplorable that the surgeon had not availed himself of the research work which had been done, instead of studying the subject empirically. A nerve divided cleanly could be sutured at once, but on the other hand when the nerve was torn by shrapnel there was retrograde degeneration and operation must be postponed.

Dr. STOKES of Omaha said it was interesting what a small amount of pressure upon the nerve was able to cut out its function entirely; when the pressure was relieved function returned. He wished to emphasize the importance of local anesthesia in peripheral nerve surgery. With reference to results following operations, he thought that frequently regaining of function was attributed to regeneration of nerve when in reality it was due to compensatory action of the muscles.

Dr. FRAZIER in closing the discussion said that the arguments which were raised during the discussion would have to remain academic for a while, the most interesting conclusions of the study would be presented later; it was too early to advocate superiority of various methods because end results would not be known for quite some time.

Immediate Sterilization of Chronic Wounds with Closure of Soft Tissues.—Dr. W. W. BABCOCK of Philadelphia presented this communication describing the method he had used for immediate sterilization and closure of chronic wounds. The method consisted of cleaning the skin in the usual form, injecting into the wound a saturated solution of zinc chloride allowing five minutes for penetration, injecting an etheral solution of methylene blue, caustic potash, and phenol, thus staining old devitalized tissues, cutting away all soft tissues and bones 1 cm. beyond the blue line and closing the wound by primary suture. He had treated with that method 64 cases of osteomyelitis, which included many cases with sinuses, and which had been operated upon previously several times. In all cases treated the injury had occurred 8 or more months before. The cases included involvement of almost every

bone of the skeleton; 78 per cent. were completely healed or progressing toward complete healing, and in 22 per cent. healing was incomplete, small openings remaining in the wound. There was no absolute failure, and in no case was there infection.

Dr. MACRAE of Atlanta said that he was fortunate enough to have seen the work of Colonel Babcock; he had seen the preparation of the patient and had followed all the steps of the operation, and he felt that the method was a real advance in surgery and that some of the results were really marvelous. He did not think that all the good results had been accomplished by the antiseptic, but that the thorough work, control of all bleeding, the deep closure, the closure of the superficial tissue without tension, and last but not least, careful splinting, were important factors in the achievement of such good results.

Dr. SARESI of New York said that the principle of using disinfection was based upon assisting nature in defeating infection and care must be exercised not to kill healthy tissues, which formed a barrier to infection. All that was necessary was to clean up the infected area thoroughly, to remove everything which entered the wound, to approximate the tissues and establish thorough drainage—not by introducing a piece of gauze into a deep cavity but by making center openings; he had used heat with apparent beneficial results. A limb could be placed in melted paraffin up to 60° C. without causing any inconvenience to the limb; paraffin drains were the best as neither blood, pus nor anything else stuck to paraffin.

Dr. OCHSNER of Chicago said he believed Dr. Babcock had given something worth while. Dr. Senn 30 years ago chiseled away the bone, filled the opening with bone chips and iodoform, and placed the limb on a splint. The speaker himself had used zinc chloride but with less striking results he had similar good results by injecting Beek's paste, which in a slower way produced similar results; an important principle was absolute rest for the limb after operation.

Dr. BABCOCK in closing the discussion said he was very glad that Dr. Ochsner had emphasized rest. Many other features could not be brought out on account of the limited time which was allowed to his paper. He expressed the opinion that the surgeon who closed an osteomyelitis wound by the Carrel-Dakin method deserved credit, but that the soldier who stood the treatment deserved a congressional medal.

Maxillofacial Injuries.—Dr. VILRAY P. BLAIR of St. Louis read this paper. He said that the injuries of the face and jaw presented no specially new problems except that they required special splints, which called for the work of a dentist. As in other wounds, infection and not the extent of the injury received was the cause of many deformities. Early and good surgery could accomplish much. It was interesting to note the rapidity of bone union after foreign bodies were removed. He mentioned several cases of very severe face injuries where good results were obtained through the cooperation of the surgeon and the dentist, while in similar cases where no cooperation existed bad deformities resulted.

Dr. ROBERT H. IVY of Milwaukee said that he had been associated with the Surgeon General's office at the beginning of the war and was later on in France. Cases were prepared so that when they reached this country plastic operation could be done.

Dr. GEORGE M. DARRANCE of Philadelphia did not entirely agree with Colonel Blair as to suturing wounds early; that should be done if the case could be left alone and watched; if the case was to be transported the wound should be approximated and drained. Skin grafting in the mouth had been successfully accomplished, the graft being held by a special splint. Patients frequently vomited, soiling the graft, but that apparently did not interfere with the results.

Dr. ROBERTS of Philadelphia said that Dr. Blair had shown that the surgeon needed the dentist. The mucous-membrane graft was one of the important things achieved through the cooperation of the surgeon and dentist.

Third Day—Friday, June 13.

War Fractures.—Dr. J. A. BLAKE of New York presented this communication, which was based on his experiences in France in treating gunshot fractures. He said that projectiles caused many types of fractures, such as simple fractures, contact fractures, partial, penetrating, and perforating, the penetrating and perforating types being the most serious ones, as they usually contained foreign bodies. Even in small penetrating wounds small hemorrhagic areas were present, leading to infection and necrosis. Fractures resulting from shell and grenade fragments always required operation, while in fractures caused by shrapnel ball operation might not be required. The object of the operation was to eliminate and remove loose fragments of bone and other foreign bodies, primary and secondary suture had been carried out by good surgeons under favorable surroundings. The Thomas splint was the most efficient one for purposes of transportation. The actual treatment of the fractures was by suspension and traction, which was accomplished by placing the limb on a movable splint, keeping it suspended by means of cords attached to the frame above the bed, and securing traction by means of weights suspended through pulleys. Lack of fixation permitting some motion between the fragments did not prevent union, but on the contrary stimulated consolidation of the fragments. The principle in carrying out the suspension and traction method was to avoid fixation, the advantage of that method being that all joints of the body could be used; no circular bandages were used. In some fractures a modification of the axis traction was necessary; the Thomas splint was the most useful for thigh and leg cases, but the splint had to be used intelligently.

Dr. MORRIS K. SMITH of New York, who had been associated with Dr. Blake in France, showed lantern slides which illustrated the method of treatment as it had been described by Dr. Blake.

Dr. RALPH T. KNIGHT of Minneapolis said that the interesting point about war fractures was the fact that the methods which were used could be utilized in civil life. He emphasized the fact that it was not necessary to immobilize the fragments absolutely in order to secure union, and called attention to the importance of mobilization of the knee joints in fractures of the femur.

War Fractures.—Major W. H. GROVES of England read this paper. He presented the greetings of the War College of Surgery of England to the surgical section of the A. M. A. He said that the great advances in the treatment of fractures were due to improvements in administrative principles, which were: segregation, continuity of treatment, and team work. It was important to secure good function and not only to perform a good operation. The muscles and joints required treatment and not only the fragments, and that treatment must be begun at the time of treating the fracture, and one should not wait for a stiff joint and then commence treatment. In fractures of the thigh, moving the patella from side to side a few times and flexing the knee as far as possible once or twice a day was all that was necessary to prevent a stiff joint. He agreed entirely with Dr. Blake's principles as to the suspension and traction method, but thought that it could be carried out in a much simpler way. He himself accomplished traction by transfixion pins introduced through the head of the tibia.

Statistical Summary of War Fractures.—Dr. JOHN B. WALKER of New York presented this communication, which was based on statistics gathered by the Surgeon General's office. He said that the statistics of treatment of war fractures had demonstrated the reliability of standard methods which he hoped all surgeons would accept. There were 5100 fracture cases being cared for in 31 hospitals at the present time. Of these 600 will require operation for osteomyelitis and 700 will require operation for malunion or nonunion; records of mortality because of infection and secondary hemorrhage showed that 4 per cent. died on the battle field, 16 per cent. died in casualty hospitals and 20 per cent. died in base hospitals.

Osteomyelitis After Injury.—Dr. PEDRO CHUTRO of Buenos Aires read this paper. He said that osteomyelitis was a national problem. There were 150,000 cases in France with suppuration of bone and about

20,000 cases in the United States. He had done about 4 years' work on suppuration of bones and until the latter part of 1916, when he began to use the Carrel-Dakin treatment, all his operations had been failures, but with the latter method he achieved good results. He advocated the use of the term bone-fistula instead of osteomyelitis, as the suppurating bone conditions of war were chronic conditions while osteomyelitis was an acute process. He thought that bone-fistula was the result of insufficient treatment at the time of injury, whether due to leaving fragments of bone or performing an incomplete operation. He emphasized the fact that bone was a specialized tissue and had very poor defense properties against infection. He advocated the Carrel-Dakin solution after the operation, and pointed out that granulations came from muscle tissue and not from bone. In his last series of 329 cases operated upon, the results had been almost 100 per cent. cure, and each case of bone fistula that came under his treatment had been previously operated upon at least four times.

Restoration of Loss of Bone from Gunshot Wounds.—Dr. FRED H. ALBEE of New York presented this communication, which was based on analysis of 100 cases in Base Hospital No. 3. He said that in cases of gunshot wounds encapsulated and latent infection was frequently present and there was danger in stirring up the infection. Therefore a minimum amount of trauma and as speedy technique as possible were important in achieving good results. He had performed a radius graft operation in 47 minutes, and the quickest time for inlaying a graft was 25 minutes; for the ulna the average time was 33 minutes, for the humerus one hour, femur 55 minutes, with the quickest time of 21 minutes. Of 48 cases of graft inlay he had 75 per cent. of perfect results with a possible 85 per cent. at the time of the operation. Microorganisms had been present at the edge of the wound, but there was practically no infection following. The success of bone grafting depended upon several points, such as the observation of the wound before healing took place, the rapidity with which wounds healed after foreign bodies had been removed, immediate operative treatment following injury, and choice of operating time for the bone graft. Some advocated not to do a bone-grafting operation before one year, but time was not the only element of safety. In his opinion it should never be done before two months after complete healing of the wound had elapsed; preoperative study of cases was required. All splints should be removed one week before operation and the ununited parts vigorously massaged, and the results carefully observed. He advocated the use of motor-driven instruments. Salt solution should be dropped on the saw while cutting was done to clear the saw and to prevent heating. The grafts should be autogenous, of sufficient length; should contain all layers of bone, should be inlaid instead of plated, and should be held by kangaroo tendon, the limb being kept in a plaster cast for six weeks.

Dr. JOSEPH R. EASTMAN of Indianapolis said that Colonel Blake had the resources and genius to apply such complicated methods as were shown on the screen, but most surgeons lacked the knowledge in physics and civil engineering to carry out those methods of treatment; much could be accomplished by simple and modified splints.

Colonel DUNNHIL of Australia said he knew of many cases where Lane plates had been used with great success; he had also heard varying reports as to bone grafting; some praised a certain method while others condemned the same method. He thought that the trouble was not with the methods but those who had used them did not carry them out properly; the various procedures had to be learned from the masters who actually introduced them. He had observed Major Albee's work and was surprised at the wonderful precision with which he used the saw and the careful attention that was given to every step until the limb was finally in a plaster cast.

War Injuries of Joints.—Dr. VERNON C. DAVID of Chicago presented this communication, which was based on his observation of gunshot knee cases in a base hospital in France. Primary operation was performed at the front and after 48 hours the patients were evacuated to the rear. Of 49 cases operated upon at the front 56 per cent. remained uninfected and 44 per cent. became infected. Infection was the most important factor in injuring the function of the joint; in cases where the capsule alone was closed following opening of the joint, 70 per cent. remained clean; where the capsule and skin had been closed 50 per cent. remained clean; knee cases with fractured articular surfaces became infected in 50 per cent.; in fractures into the knee joint of one or both condyles, the articular surfaces were removed without serious loss of motion to the joint and there was no infection. In the after treatment of infected joint cases Willems' active mobilization method was used in every case with very good results. If drainage had to be instituted lateral incisions were made; in gunshot injuries of the knee where the joint had remained noninfected 70 per cent. of the cases had normal motion. The good results were due to the active mobilization of the joints.

Dr. ARTHUR M. SHIPLEY of Baltimore said that he observed gunshot knee injuries during the Argonne offensive. It was the practice there to close the joint if it was possible to explore it without exposing muscle tissue; ether was used for cleaning the joint; if a bullet entering the joint did not go through muscle tissue primary suture was done; if the muscle had been entered, the joint could not be closed by primary suture.

Dr. BURTON J. LEE of New York said the greatest contribution to surgery the war brought out was that to knee surgery. In the A. E. F. results had been poor because mobilization of the joint had not been practised continually. The point Dr. Shipley had made not to close a joint when muscle was exposed was a very good one; otherwise primary closure gave good results, septic joints offered no contraindication to mobilization; they had many suppurating joint cases with normal function due to mobilization. In all septic joint cases the patients were awakened every two hours during the night and made to move their joints.

Dr. KELLOGG SPEED of Chicago said that operative interference in joint injuries should be insisted upon, and the operations should be standardized. In the case of fractures into the joint it was not necessary to perform excision; the time elapsing between the occurrence of the injury and the operation was an important factor in determining the results. His observations were the same as those of Dr. David, that it was best to close the wounds when possible, even when there was loss of synovial substance. There was a higher mortality in operations following infection of the femur than in those following infected knee joints, for the pain in the knee joint brought the infection early to the physician's attention.

Dr. BLAKE, in closing the discussion, said he could not agree with some of the criticism regarding the complicated form of his method of treating fracture; he thought on the contrary that the method was a very simple one. The objection he had to any apparatus which rested on the bed was that the method always had a degree of fixation; either fixation or nonfixation should be used. If there was even temporary fixation harm could result, for if the attempt was made to mobilize a joint after a few days, when healing had begun, traumatism would result. He agreed with Dr. Albee that nothing foreign should be used in bone grafting; he also thought that the Section on Surgery had made a mistake in calling the suppurating bone conditions of war osteomyelitis, which was an infection of the medulla and was rare in war conditions; in the war cases there was bone necrosis, and he quite agreed with Dr. Chutro in calling the condition bone fistula.

Brain Injuries.—Dr. HARVEY CUSHING of Boston presented this communication, which he illustrated by means of lantern slides. He said it was important in cranial injuries to close the wound, and in consequence the neurosurgeons had been the first to employ primary suture; local anesthesia was used. A triangular incision was made, a block of bone removed and a catheter to which a Carrel syringe had been attached was used to remove by suction all foreign bodies from the wound, and the wound was then closed. For purposes of study they divided all injuries of the brain into eight classes, as follows: (1) Scalp wounds without injury to the

bones of the skull. (2) Scalp wounds with bone injury, either the inner or outer table being involved, but with the dura intact. (3) A more serious type of injury, where the dura was punctured but with no serious involvement of the brain tissue. (4) Where brain substance was involved. (5) Where pieces of metal or bone were driven into the brain tissue. (6) Where metal or bone had been driven into the fourth ventricles. (7) Where the frontal sinuses were opened, leading to infection of the middle ear. (8) Perforating wounds of the brain. The scalp wounds were not to be taken lightly, as very serious consequences frequently resulted from such wounds. With proper attention, however, groups 1, 2 and 3 caused a very light mortality. Groups 4 and 5 were more serious, and the other groups gave a quite high mortality.

Abdominal Injuries.—Dr. GEORGE W. CRILE of Cleveland presented this communication. He said that the greatest difficulty in handling abdominal injuries at the front was to know where to locate the casualty station. The abdominal cases had to be treated early, as after ten hours following injury the mortality was very high, and in twenty hours after injury the case was almost fatal. The station could not be placed too near the front, as the hospital was apt to be destroyed or it would require frequent transferring of patients to stations further in the rear. The good results the surgeons in France had with cases of abdominal injuries were in part due to the fact that the patients represented the best type of men, whose resistance had been greatly accelerated. Death from peritonitis was rather rare. In injuries to the liver no operation was attempted, injuries to small intestines gave better prognosis than those of large intestines. It was very interesting to note how in a combined wound of the chest and abdomen the stomach or other viscera could be removed through the opening in the chest. Shock and hemorrhage were the great causes of the high mortality; he did not think that anything new had been brought out in the treatment of shock and hemorrhage. At an interallied congress of surgeons which was held after the signing of the armistice it was the official opinion that combined nitrous oxide anesthesia with local infiltration was the method of choice in cases of shock and hemorrhage requiring operation. Captain Taylor of England had performed 181 laparotomies; in nearly one-half of the cases nitrous oxide and infiltration anesthesia had been the method used, there was a reduction of mortality from 50 per cent. to 29 per cent., which Dr. Crile thought was the best record obtained by anyone. He said that he had learned one thing, and that was to employ blood transfusion early. It was the custom in civil life to look upon blood transfusion as a last resort, which he thought was a great mistake. The time of the operation was the important factor in obtaining results. In dealing with peritonitis with very grave injuries large doses of opium plus large amounts of salt solution subcutaneously was the treatment used. In suturing intestines the difficulty was to use a suture lightly enough; no drainage was used in small intestinal operations but drainage was used in operations on the large intestines. His experience in France showed that the principles of military and civil surgery were the same—early operation, careful technique, and attention to post-operative details gave the best results.

Placentomas and Choriomas of the Testicle.—Hartmann and Peyron refer first to the old term "teratoma" of the testicle. Originally these were stated to contain only fetal parts. At a later period authors began to write of chorioepithelioma of the male gonad. Then growths analogous to placentomas of the uterus were recognized and appeared to be due to traumatisms in many cases. They were highly malignant, showing a tendency to rapid generalization. Metastases were almost always hemorrhagic. The placentomas are not akin to the teratomas, but have doubtless passed for special types of sarcoma. In certain cases the breasts swell and colostrum appears. The variety known as chorioma is evidently a variant of the seminoma—that is, many of the latter merit the term chorioma. In discussion there was objection to these new terms. —*La Presse Médicale.*

Miscellany.

The Journal of a Vaudois Surgeon in the Army of Marshal Saxe 1746-1747.—This document has recently been published and the following extracts from the volume are taken from a review of the same in *Le Progrès Médical* for May 10. In 1746 one F. B. Pictet, practitioner of medicine in Mondou (in Vaud) was looking for a new locality where patients were more numerous and with better pay. War was then reigning in Flanders and he decided to enlist in the service of Louis XV who gave him a commission as surgeon. Much preliminary work had to be done both to close up his affairs as a civilian and to fit himself out for his military work. He was authorized to collect his bills and pay his debts and ordered to make out an exact inventory of his personal belongings, etc. This included his equipment for the practice of medicine and surgery. Other articles were for his personal use (uniform, etc.). Certain articles (pistols) he had to get of an armorer. It took about 10 weeks of preparation before he joined the army and was assigned to his regiment. The latter left Tournay and soon reached Brussels and the surgeon was quickly on the battlefield. With three colleagues he was assigned to a dressing station. He took part in battles, a siege and in one massacre. The latter shocked him greatly as shown by the entries in his diary. He treated civilians on whom he was quartered and mentions that dysentery was endemic in the country. On the way back he stopped with his regiment at Liège and made a study of conditions. Here he paid 30 sous for two large cups of coffee and 10 sous for a quarter pound of smoking tobacco. He was demobilized or resigned from the French army at Tongres just in time to see the King at dinner in a tent. That he did not miss this experience gave him great satisfaction. His diary stops here and we only know that in 1761 he was living in Lausanne with no further desire for travel. He had seen enough to last him for life.

Vulgus Vult Decipi.—Barnum's dictum that "the public likes to be humbugged" was anticipated by many centuries when the ancient heathen priests in offering a holocaust justified the act by the statement that since "the public wishes to be deceived, then let it be deceived" (*vulgus vult decipi, ergo decipiatur*). Trombetta, the learned and brilliant editor of the *Giornale di Medicina Militare*, in the June 1 issue, goes at great length into medical charlatinism, beginning with a reference to the "dulcamara" or universal remedy for all ills. In dilating on this subject the author cites several separate versions of the above proverb, from which it appears that the words *mundus* and *populus* are sometimes substituted for *vulgus*. Whatever the origin of the phrase it represents a profound truth and the author in a very small compass recounts most of the great medical swindles of the past few centuries, chiefly wonder-working drugs which were either panaceas or specifics. Some of the masterpieces of literature are devoted to the exposition of pretenders to medical skill in which legitimate practitioners were sometimes included. Occasionally some much reviled alleged cure-all made good, as in the case of ipecacuanha.

SIXTY YEARS OF MEDICINE.*

BY ALEXANDER LAMBERT, M.D.,

NEW YORK,

PRESIDENT OF THE AMERICAN MEDICAL ASSOCIATION.

MR. PRESIDENT, Ladies and Gentlemen:—Threescore years ago a group of physicians met together to found the institution whose anniversary you meet here to-night to commemorate. Among them were men of high scientific attainments, such as Doremus and Dalton, and others who had acquired not only, to a high degree, the science of medicine, but who moulded the knowledge thus acquired into the daily routine of the healing art of medicine. Such a man was Austin Flint, Senior. This group of men builded better than they knew, for they evidently foresaw that the secret of a teaching institution must rest on that combination of hospital and college which has always characterized your institution. The spirit in which this institution was founded, and the intention of its founders, is clearly shown in their first prospectus published. There it is stated that

> In the establishment of this public charity it is proposed to furnish:
>
> 1. A hospital with an in- and out-door department, for the treatment of medical and surgical cases.
> 2. A lying-in department for the poor and unfortunate.
> 3. A corps of regularly educated and licensed nurses.
> 4. A college where all the branches of medical science shall be taught and illustrated, and where medical students can be practically trained.
>
> In England, France, Germany, and our own country it has been practically demonstrated that a hospital where medical education is not carried on very rapidly degenerates and soon fails to represent the average standard of medical science, while colleges without hospitals to illustrate their teachings become theoretical, and produce men untrained and unequal to the practical demands of the community.
>
> The science of medicine has advanced, by the united efforts of thousands of minds in different quarters of the globe, through a succession of ages, and by slow and difficult steps, to the present standard. It is even now kept alive by the self-sacrificing labors of the comparatively few. To make this knowledge grow, spread, and reproduce itself in a community, it must be fostered and encouraged. This can only be accomplished by the establishment of institutions where the science of medicine can be cultivated to advantage, and practically tested and taught.

Such expressions of standards and intentions are as valid to-day as they were sixty years ago and still stand as the expressions of attainments to be hoped and to be struggled for. This college may well indeed be proud that it was the first institution in this country to build and have function a laboratory devoted to bacteriology and scientific sanitation, which are the foundations of all the preventive medicine of which the profession is so proud to-day. From its origin it has always, through the members of its faculty such as Skene and McCorkle, interested the public in its growth, for through men such as Skene and McCorkle has the daily care of the physicians in families and homes been best expressed in the community, and the community of this city, recognizing the infinite care and friendship bestowed, has, in its turn, at the request of these men, given generously and increased enormously the opportunities for medical care and protection to the less fortunate members of the community, and to the very poor needing hospital protection.

More than this, from the very beginning the founders of this college realized, and their successors have practically shown, that any large hospital must have and develop a training school for its nurses, in order that its sick may be adequately cared for in the wards of its hospital. It is evident that the lessons of a terrible war were still fresh in the minds of the founders of this institution when they promulgated that third sentence, that they proposed to furnish "a corps of regularly educated and licensed nurses." The Crimean War had ended a few years before, and in the Crimean War the work of Florence Nightingale had stimulated and founded the ideas of the practical training of nursing which has developed that profession of to-day. The lessons of that war had not been forgotten; they must have realized that, in spite of the battle casualties, the terrible death rate of disease had been appalling. For the death rate from battle in that war was the greatest among the Russians, and the death rate from disease was the greatest among the French, of any of the wars of which we have accurate statistics. England had forgotten the lessons of the Napoleonic Wars and had sent her army to the Crimea unprepared, badly equipped, and hopelessly handicapped to fight against disease. The French, at first, were better equipped, better rationed, and better prepared to meet the situation. Excluding battle casualties, during the first winter of the war the English lost a third of their fighting force from disease alone. The French suffered much less severely. Then came the reaction in England. Adequate and proper supplies were hurried to the Crimea. Florence Nightingale, accompanied by the devoted women who assisted her, was sent into the hospitals, with the result that, in the following six months of the war, while

*An address delivered at the sixtieth annual commencement of the Long Island College Hospital, Brooklyn, N. Y.

the English lost but some 950 men from disease, the French lost 10,000, and in the last six months of the war the English lost but 218 men—which was practically the same death-rate as among their troops at home, but the French again lost some 8,000 from disease alone. Such was the result of sanitation and nursing in the English hospitals, and such was the result of faulty organization in the French army, expressed by the domination of a lay staff over medical matters.

Whether or not the lessons of this war, through the publications of Surgeon-General Longmore of the British army, were known to the founders of this college, we cannot say. Certain it is that they grasped the meaning of events that had just occurred and foresaw the necessity of the development of hospital care and of improvements in nursing. Although the first training school for nurses in this country was not established until a generation later, the realization of the need, and the intention, was clearly expressed. One must grant them the courage of their convictions, or must grant them vision, or even both.

It is hard to think in terms of sixty years ago. It is difficult for us to think the thoughts of men of that time or of their environment. Brooklyn then was a city on the Heights, extending over comparatively little of the great area it covers today, just as New York practically stopped at Twenty-third Street, for at that time in New York there were no houses between the old Fifth Avenue Hotel and the old Reservoir at 42nd Street, which you all easily remember. A few revolutionary houses dotted the landscape, but beyond that New York had not grown. The communication between Brooklyn and New York was by horse-drawn vehicles across the ferries, and it was necessary that students in Brooklyn should have their own medical school and hospitals, or else leave their homes and go even the short distance to New York and live there, to obtain a medical education. The founders of this institution, therefore, were founding a communal necessity, a hospital for the sick and a college in which the best medical teaching of the time could be given.

In the scientific thought of the day it is not easy for us to appreciate the change that has occurred. It was in the year 1859 that Darwin published his book on the "Origin of Species," and certainly not for three hundred years, probably not since Copernicus demonstrated that the planets revolved around the sun and that the world was not the center of the universe, has there appeared a scientific theory which so rearranged and altered our scientific conception of the universe. Many of us can easily remember the bitter controversies over "Darwinism," as it was called, that raged during our boyhood. If we wish to look at scientific matters as the founders of this school had been taught to look, we must consider them with all our conception of evolution and with all our conception of an orderly development of the universe left out. Our ideas of progressive development must be put aside.

It is also extremely difficult for those of you who are just finishing your medical course to realize that the medicine taught in this school sixty years ago would have omitted all conception of antiseptic or aseptic surgery, all conception of antitoxins and the ideas of immunity with which you are so familiar, all conception of bacteriology and of sanitation founded on the control of infections from these sources. Virchow had only just published, a year previous to the founding of this school, his book on cellular pathology which had taken the conception of the body out of the humoristic theories, and had given a new point of view from which to consider it. For Virchow showed that the body was a cell-state in which every cell is a citizen, and of course the health of every cell is a matter of concern to the whole state, and that disease is merely a conflict of citizens in this state, brought about by the action of external forces. That was a fundamentally new conception, and while it needed the work of Schultze and others further to differentiate and define each cell and its contents, a foundation was laid for pathology, as radically different from the past as when William Harvey laid a new foundation for physiology in his proof of the circulation of the blood. The development of the normal structures and the morbid changes that occur in cells has since gone on to such a degree that practically, today, it is possible for students to learn, and doubtless you know more about the changes in the individual cells of the body in health and disease than your teachers possessed sixty years ago about such changes in the entire body.

Imagine walking through the surgical wards before the days of antisepsis. Imagine every wound "suppurating nicely," the only question being how "laudable" was the pus. It is hard for us to realize today that the mortality of amputation of the toes or fingers was 3 per cent., and that almost all compound fractures of the thigh were bound to kill from sepsis. Going through the medical wards in those days, there were the urinary examinations recorded, but beyond that the clinical pathology and the laboratory work did not go. Another generation was to pass before an accurate knowledge of the blood and the meaning of its intricate changes of the cells in various diseases, was to come. The diagnosis rested on the experiences of the man examining and interpreting, from accurate and minute observations, the various changes, according to what he knew the body should show in health. A careful physical examination, a shrewd look with unconscious reasoning, and the diagnosis would be given, based on minute changes that those of lesser experience could not understand nor see. To see Flint or the elder Janeway, thirty-five or forty years ago, come in to a patient, go carefully over him, listen to what could be obtained of a history, and give a diagnosis with a marvelous accuracy, with no aid of clinical pathology as developed today, would seem little less than uncanny to the modern student. The great expansion of laboratories has developed with it a reliance on chemical and microscopic tests, rather than on the shrewd observation of minute differences of patients sick with the various morbid processes which we know as diseases. The mental attitude has grown up among the young practitioners that, unless a patient shows every laboratory test possible, he cannot be suffering from a certain disease. The pendulum today has swung clear to the other edge of its arc, from the time when our former

teachers taught us to diagnosticate the various diseases without clinical pathology. And while there is always a greater accuracy today, in the careful multiplicity of tests, there seems to be an inability to realize that diseases are not entities, and that they are but morbid processes varying in intensity, varying in different points of the body through which the morbid processes show themselves, and that diseases are but the combinations and permutations of the perversions or cessation of normal functions. As, for instance, it is possible for a patient to be suffering from typhoid fever, and yet not show every possible blood reaction that chemistry and bacteriology can produce in that fever. It is possible for a patient to be suffering from typhoid, yet not show the typical rash nor every symptom that has been noted in some treatise on that disease. But such is the tendency of the human mind to shift responsibility of a decision. that the student of today is in danger of relying more on the laboratory tests than he is on the signs and symptoms shown in the patient, and to put off the responsibility of a diagnosis upon the man in the laboratory rather than to accept the fact that he must make his own diagnosis at the bedside of his patient. In the future, the young men going into the profession must be taught that greater intelligent harmony between the clinician and the laboratory expert must be developed, by which the clinician will appreciate more the value of the physical signs and symptoms of the patient, and realize that the negation of laboratory findings does not rule out the existence of a disease; and the laboratory workers must study and develop our knowledge of the probability for and against the occurrence of any given test under certain circumstances.

It would be interesting to trace the great development of scientific medicine in the last sixty years. That would be particularly fitting for an audience limited to physicians, but it would necessarily be extremely technical. It is better, therefore, that we leave that fascinating side of the growth of medicine, and turn to the application of this science. Let us consider for a moment what we have gained in the control of the struggle against disease in the last sixty years.

Vaccination against smallpox was, of course, known and practised, and had practically controlled that disease in communities. There was a realization that when vaccination was carried out the disease ceased, but, through carelessness in communities, every now and then an epidemic swept over a country, to remind it that the disease was still present and that if the sin of omission was committed it would recur with all its old-time intensity and horror. One of the greatest examples of this was the epidemic of smallpox which followed the Franco-Prussian war in France and Germany. Both countries had excellent vaccination laws, except that they were not compulsory, hence many carelessly remained unvaccinated; and the herding together of the armies of that war started an epidemic which cost those nations 170,000 lives. The Civil War which broke out in this country shortly after this College Hospital was founded, gave an opportunity for public service in the care of the wounded, of which this hospital was quick to avail itself. As far as any exhibition of preventive medicine was concerned, the science of medicine had not sufficiently developed to show itself in the surgery, and in the sanitation and prevention of disease, at that time. Antiseptic surgery had not been conceived, and the prevention of infection could not be practised. There were no great epidemics of disease in the Civil War. Malaria disabled thousands of men, but was controlled by quinine. Dysentery and typhoid occurred in steady numbers, but not in any great epidemics. Pneumonia, meningitis, and yellow fever all were present, but not in large numbers. Measles developed in the camps and spread among the young men, and ceased from lack of more persons to infect.

A generation passed, and antiseptic surgery had become firmly established and developed. The ideas of infection and its prevention, the knowledge of bacteriology had developed so that sanitation could control disease. With accurate ideas of how diseases are transmitted came also the realization of how they could be prevented, and simultaneously came the responsibility for the prevention. When the epidemic of typhoid fever, therefore, swept through our small army in the time of the Spanish war, the country was shocked, for over 60 per cent. of the deaths from disease of that war were produced by typhoid fever. Out of the bitter lessons of the Spanish war came the knowledge gained at that time, that typhoid not only can be transmitted by water, but occurs in camps, in the majority of cases, through contact from man to man and hand to hand, in the healthy helping the sick. Sanitation, without doubt, gave control in a great measure, but something further was needed. Following the Boer war and the experiences gained therein, inoculation by vaccination against typhoid fever, became possible. Thus typhoid has become absolutely controllable, and one former scourge of war has ceased to be a factor of disease to be reckoned with in warring armies.

There is one group of diseases through whose control great practical results, of world-wide value, have been obtained. I refer to those diseases transmitted to man through insect carriers. Malaria and yellow fever are transmitted by mosquitos. The dreaded typhus fever—that is, the old jail fever, spotted fever, brain fever, Hungarian disease, famine fever, call it what you will—which has again and again decimated all Europe with its epidemics, is transmitted by the bite of body lice; and recurrent fever and trench fever are communicated by the same insect. Bubonic plague is given by the bite of fleas. The control of malaria and yellow fever alone made possible the building of the Panama Canal. And, more than that, it was only through the application of medical scientific knowledge that that great engineering feat was achieved. The great skill of De Lesseps was rendered powerless because malaria and yellow fever were, in his time, uncontrollable. The skill of Goethals succeeded because the knowledge of Gorgas preceded and accompanied him.

It was given to some of the founders of this school to live long enough to see many of the developments of recent times. Flint lived long enough to know that the tubercle bacillus was responsible for the changes in the infection of tuberculosis.

Sitting on the porch at Bellevue Hospital, one afternoon in the last years of his life, he turned to some of the younger men and said, with a quizzical smile, "I envy you men. You are going to see, in the next ten years, a great many things develop, and you are going to have the pleasure of solving a great many questions that I have been puzzling over. I wish I could see them."

To Flint and Dalton the profession owed a peculiar debt. These men produced books that made the study of medicine a pleasure to the student. Most books are but the compilation of other men's knowledge. But once or twice in a generation is a real medical book written. These men produced such a book, lightening the labors of other generations, mapping out, as far as in them lay, a royal road to learning.

Over thirty years ago, when I myself graduated, the giver of the address that evening was none other than John C. Dalton. An old man, still rugged and of vigorous intellect, he looked back upon the experiences of his lifetime. He had seen ether first given as an anesthetic in the Massachusetts General Hospital, and, as an assistant to my uncle, Alfred Lambert, the house surgeon, they two had cared for the first patient to whom ether had been given. They had experienced the agony of watching operations when patients were strapped down against the terrible pain of preanesthetic days, and had seen the enormous possibilities develop in surgery through the giving of anesthetics. Dalton, in turn, had seen the preantiseptic days and had seen antiseptic surgery develop, and his description made one realize that he had lived through and seen grow under his eyes two great epochs of surgical advancement. He spoke as a dignified sage, of the past, and in his charming diction made one of the most memorable addresses that it has ever been given to me to hear.

In the generation that has passed since I graduated, there has taken place, not only the enormous growth of scientific medicine and scientific knowledge in the medical profession, but this has developed in all branches and specialties in medicine so that it is no longer possible for one man to confine himself to the whole subject. A normal, healthy specialism in medicine has come and must necessarily remain, for the development of the various specialties has been so great that, in the span of life allotted to each one of us, there is but time to master the specialty that we choose, and that only through unceasing and never-flagging diligence. The individual development in medicine must necessarily go on, for through the development of the individual must scientific advance in medicine be produced. But, with all that, the old order is changing, and we are today in the presence of a distinct rearrangement. The profession of medicine has ever been a very individualistic one, but the future development must come through a greater sense of cooperation and a greater sense of acting in groups, that through the production of the group action the best art of medicine may be produced. The strongest team in your athletic experience is that made up of the best individual players, who, through great individual ability but with perfect group cooperation, act together. And so, it seems to me, will be the future in medicine. There will be the same individual development and the same opportunity for individual excellence as today, but the art of medicine as given to the public will be more through cooperation of many men than through individualistic action. It is a common saying that the family physician is passing, the family friend to whom the troubles and trials of the family were known, and on whose advice in things medical and things temporal the family learned to depend. The old physician, who seemed to the children as possessing medicine as a forte and omiscience as a foible, may be passing, but sorrow and joy are ever personal, and the relation of the physician to his patient must ever remain equally personal. And as long as sickness and accident and the troubles of mankind will remain individual and personal, as they must, just so long will the profession of medicine help and deal personally with the individual in those times of trial. There are some relations of mankind that vary in details of experience, but in essentials do not change, and it seems to me that the relation of the physician to his patient is one of these.

Young gentlemen of the graduating class: It is my pleasant duty to welcome you tonight into the ranks of the medical profession, and I suppose it devolves on me also to give you some advice. Permit me, therefore, to transmit to you the advice given to me by my preceptor, the late Henry B. Sands, one of the really great surgeons of his time. Do not permit yourselves to become mentally lazy, never cease to study. To acquire knowledge is easy, but your success in life will depend upon digesting that knowledge, and turning it into medical wisdom, and applying it in the healing art of your profession.

Remember also that you have entered a profession which possesses high standards and ideals, and has retained its ethics as a living force. I do not mean by medical ethics any queer old prehistoric formulæ. Every profession has its own customs and conventions, which often are thought to be its ethics, but are only enforced by public opinion because experience has shown it is the line of least resistance through which to attain some desirable end in human relations. But I do mean the standards of the Golden Rule of life, of upright living, of common everyday honesty and righteousness, and the square deal one to another in your professional relations. The medical profession has retained those ethics, and these are the standards it requires you to live up to. And remember that opportunity is all that will be given to you in this life. Success will not be handed to you on a golden platter.

The word "opportunity" invariably brings to my mind the memory of some fifteen years ago, when one day I stood in Washington, in the Executive office of the then President, Roosevelt, waiting for him to finish some work. I saw hung on the wall a framed sonnet of John Ingalls of Kansas. It was called "Opportunity," and ran as follows:

Maker of human destiny am I,
Fame, love, and fortune on my footsteps wait.
Cities and fields I roam; I penetrate deserts
And seas remote. And passing by palace
And mart and hovel, soon or late
I knock unbidden once at every gate.

If sleeping, wake! If feasting, rise!
Before I turn away. It is the hour of fate,
And those who follow me
Gain every desire and conquer every foe
Save death. But those who doubt
Or hesitate, condemned to misery,
Penury, and woe, seek me in vain
And uselessly implore. I answer not,
And I return no more.

* * * * *

Young ladies of the graduation class of nurses:—To you also it is my pleasure and duty to address congratulations and, I suppose, some advice. You need have no fear but that you have ahead of you, in following your profession, busy and useful lives. New opportunities for your activities are opening out each year, in Public Health work, in social service, and in collateral lines of your profession; and the work for which your profession was originally founded, that of individual care of the sick in hospitals and homes, has ceased to be the only work of your profession. Your opportunities for great usefulness are increasing, it is true. But the community is beginning to ask that the original purpose of your profession should not be overlooked in your choice of work. In the practical work of nursing it has seemed to me that one of the traits of character leading to the greatest success is adaptability to different environments. Cultivate, therefore, your abilities to lighten the burdens of your patients' situations, and be careful that you do not unconsciously add to these burdens. In the coming rearrangement of this disorganized world you will have many interesting experiences and opportunities for usefulness, and I wish you, every one of you, success.

43 East Seventy-second Street.

SOME FACTS AND PRINCIPLES OF DIETOTHERAPY.

By EDWARD E. CORNWALL, M.D., F.A.C.P.

BROOKLYN, NEW YORK.

Dietotherapy is a very old branch of medicine, perhaps the first to show scientific development. Savage man, like the animals, learned to stop eating or to change his diet when sick. Hippocrates devotes thirteen of the first nineteen of his aphorisms to dietetic subjects. But dietotherapy has not kept up the pace of its early promise, and although at the present time we have a large accumulation of facts bearing on scientific dietetics, the practical application of these facts in the treatment of disease, except in comparatively few instances and by a limited number of the medical profession, appears much neglected. If we examine recently published text books on the practice of medicine we find the directions given for diet for the most part meager and vague. The attitude of most physicians toward dietotherapy reflects in its indifference to the relatively low esteem in which this undeniably important branch of medicine seems to be generally held. Most physicians know little about diet and care less. And our best medical schools continue to turn out graduates unable to write even a quantitative dietetic prescription, which is an elementary matter, to say nothing of writing one which shall also be balanced and qualitatively appropriate. The recent graduate, as well as the old practitioner, is still apt to confuse the practice of medicine with the use of drugs to an extent which I feel sure will soon be universally recognized as unduly large. We are now living in an epochal period of the history of medicine; a revolution is going on in medicine, which among other things is changing the face of therapeutics. But I must not digress into medical philosophy, but get on with my subject of dietotherapy, which, by the way, occupies no insignificant place in the revolution to which I referred.

In modifying the habitual health diet of a patient in such manner as to favor his recovery to health, which is what we mean by dietotherapy, we must first of all have due regard for that fundamental and universal principle of dietetics, the principle of adequate nutrition: the patient must get enough to eat. No dietetic plan can be suitable which, except temporarily and for a special purpose, disregards this principle. I find it necessary to emphasize this self-evident principle because in the pursuit of some special therapeutic object the tendency to disregard it may easily exist; and it may be disregarded from carelessness or ignorance; and it often is disregarded. Sick people are often not only fed improperly but fed insufficiently. This is so extensively the case that patients in general are likely to express the fear, when put on a diet, that they are going to be starved. In popular estimation dietotherapy is almost synonomous with starvation.

A diet to be adequate must be properly balanced. The so-called caloric feeding, which aims to supply sufficient fuel, is not necessarily adequate. Even sufficient quantities of protein, fat, carbohydrate, salts, vitamines, and water may not constitute an adequate diet. The various food principles themselves may require internal balancing. This is particularly the case with the protein ration. Not all varieties of protein are of equal value as food. If the patient is given only the protein of bread, for example, which is almost entirely glutenin and gliadin, he must eventually starve: man may not live by bread alone. Protein, from the point of view of nutrition, appears as the component amino acids into which it is split up by digestion. These amino acids differ in different kinds of protein in number and variety as well as relative proportions. The body requires certain quantities of a certain number of different amino acids for its adequate nutrition; and, if its nitrogenous economy is to be favored, it must have them in certain relative proportions, viz., the proportions in which it can fully utilize them. The balanced diet, then, requires that its protein, or a considerable proportion of it, be protein which parallels the body needs as regards the amino acids which it supplies. Such perfect protein, so to speak, is found practically only in animal flesh, eggs, and milk; and the balanced diet must therefore contain a considerable quantity of one or other of these articles. Herein appears an effective argument against a strictly vegetable diet: theoretically it is possible by combining different protein-containing articles of vegetable origin to get all the amino acids required, but practically it is extremely difficult to make such supplementary combinations that will be satisfactory.

The balancing of the fat ration is not ordinarily

difficult. The soft fats and oils should largely predominate, and it is desirable, though not absolutely necessary, that some butter fat be included in the ration, because of its easy digestibility, its vitamine content, and its agreeable taste, in which respects it surpasses all other food fats.

The balancing of the carbohydrate ration is easily accomplished. In it starch occupies the chief place, except in the diet of infants. Our body, considered as a furnace, seems specially adapted for burning starch. Sugar occupies an inferior place, and in the dietary of invalids a much inferior place. Cane sugar, which is the sugar commonly eaten, is an exotic in our regular diet. It is interesting to note that cane sugar became a large element in our diet only during the last four generations, which is a short time in which to become used to a new food. Four generations ago it was too expensive to be used except as a luxury. Its present cheapness, together with its superior sweetness, has contributed to its popularity. The present per capita consumption of cane sugar in this country is estimated to be a quarter of a pound daily. It is perhaps the most susceptible of the common sugars to yeast fermentation. Milk sugar, which is also a disaccharide, is less susceptible to yeast fermentation, but is the most susceptible of all the sugars to fermentation by the lactic acid bacteria, which is sometimes an advantage. Lactose is the special carbohydrate provided by nature in milk for the diet of infants. The monosaccharides, glucose and levulose, while less objectionable than cane sugar, are also notably susceptible to yeast fermentation. A general objection to all sugars taken in large quantity in the diet, is that they may be absorbed so quickly that flooding of the portal circulation takes place, which overtaxes the glycogenic function of the liver. Sugar can also disturb digestion, especially in concentrated solution. One advantage of starch as a carbohydrate food is that it is digested with comparative slowness, so that its absorption is spread over a considerable period. There are, it should be noted, differences in the digestibility of different starch foods. In the carbohydrate ration of the sick adult sugar should occupy a comparatively insignificant place, with the preference among sugars being given to lactose, nature's favorite. Here I would like to say a word of warning against the excessive restriction of starch in non diabetic conditions, which appears to have become something of a fad.

The balanced ration of salts usually takes care of itself in the ordinary mixed diet, with the addition of a small quantity, not more than two or three grams daily, of sodium chloride, and even this addition may not be absolutely necessary, though certainly conducive to comfort. In order to insure the proper balance as well as quota of salts, the diet should include a considerable amount of fresh vegetables or fruits, or milk, all of which are particularly rich in the salts needed by the body. In some conditions there is a call for extra quantities of particular salts. Iron may be required in extra quantity, and it can be supplied by adding to the diet the isolated element or one of its salts, or by increasing the amount of the natural articles of food in the diet which are unusually rich in iron. Examples of such articles are: lean meat, eggs, oatmeal, whole wheat, and green vegetables. Milk contains only a small percentage of iron, but that is in a most assimilable form. Lean beefsteak, spinach and oatmeal contain about equal percentages of iron. Another salt of particular importance, and one in which an asymmetrical diet may easily be deficient, is calcium. The most available source of calcium is milk, which contains fifteen times as much of this element as does lean beefsteak. Milk is also rich in potassium, though less so than the green vegetables, cereals, and potatoes. Milk, indeed, contains all the salts which the body needs in more nearly a balanced ration than any other largely available article of food. It is well to know that one quart of milk contains about one and three-quarter grams of sodium chloride, and when it is desirable greatly to restrict that salt, large quantities of whole milk should not be given.

A feature of the saline balance which is of fundamental importance is the maintenance of the alkaline reserves in the body. It is a condition of the life of the tissues that they be bathed constantly in an alkaline fluid, and a reduction in the alkalinity of the body fluids below a certain point means acidosis, which is a constant chemical menace to health analogous to the biological menace of the pathogenic bacteria. This necessity for maintaining the fluids of the body as solutions of alkaline salts would seem to hark back to the primordial era, when man's unicellular ancestor began existence in the ocean. When in the course of ages our ancestors, more developed, came out of the ocean to live on dry land, they dragged with them a skin bag of fluid not much dissimilar to sea water; and at the present time our body appears as a bag of such fluid with the tissues floating around in it. In arranging a dietary so as to insure a safe alkaline margin, we must bear in mind what articles of food decrease the body's alkalinity and what increase it. Animal flesh, eggs and cereals, when finally burned up in the body, show an excess of acid-forming over base-forming elements, while milk, fruits, green vegetables and roots show an excess of base-forming over acid-forming elements. It is evident from this that a diet exclusively of bread and meat, while it might be correctly balanced as regards its protein, fat and carbohydrate, would not be so as regards its salts, but would invite acidosis, unless the body could manufacture enough ammonia to neutralize the acid.

The balanced ration of vitamines, those mysterious substances which are necessary to enable the body to utilize its food, requires inclusion in the diet of sufficient quantities of articles containing the two classes of vitamines, which are known as Fat soluble A and Water soluble B. The former can be supplied by butter and milk, and the latter by cereals and green vegetables. Milk and eggs are both particularly rich in both classes of vitamines, and among vegetables, whole cereals, cabbage and potato deserve special mention for their vitamine content, particularly of the water soluble varieties. A diet which includes a whole wheat bread, butter, green vegetables, potatoes and fresh fruit in fair amounts, would give a balanced ration of vitamines; and so would one which includes a large quantity of milk.

Another principle which, like the principle of

adequate nutrition, is of universal application, and which is of paramount importance in dietotherapy, is the principle of the easy diet. The easy diet may be defined as one which reduces the necessary wear and tear of adequate nutrition to the minimum practicable in the particular case. It has to do with the quantity and quality of the food. In health the reserve powers of the organism permit a considerable excess of food as well as a considerable latitude in regard to hard foods, but in disease such excesses cannot be so well taken care of. The quantity ideal of the easy diet in most cases is the minimum health ration. Reduction below this minimum and increase above it may be called for in accordance with the dietotherapeutic principles of starvation and suralimentation; but only temporarily, so as not to do violence, in the case of starvation, to the principle of adequate nutrition, or in the case of suralimentation, to the principle of the easy diet.

An essential consideration in the easy diet is the quality of the food, that is, the character of the articles which are given to supply the patient with his quotas of protein, fat, carbohydrate, salts and vitamines. The same food principles occurring in different articles are not necessarily physiologically equivalent; and the composition and special characteristics of the different articles must be considered with reference to the reactions which occur between those articles and the organism after ingestion. Different articles of food may resemble each other in their content of food principles and from the point of view of quantitative dietetics be equivalent; but from the point of view of what happens to them and in consequence of them in the body, they may show differences which are important in respect to the easy diet. Boiled spinach and boiled cabbage may appear as green vegetables of similar composition, but their behavior during digestion may bring out marked differences: the latter belongs to a small list of vegetables which are rendered more indigestible or more disturbing to the alimentary tract by cooking. Milk sugar and cane sugar supply the same number of calories, weight for weight; and both belong to the same group of disaccharides; but they may act and be acted on somewhat differently in the body: the former is more susceptible to fermentation by the lactic acid bacteria, and the latter by the yeast bacteria. An ounce of cottage cheese and an ounce of lean steak contain nearly the same amounts of protein, and the same kinds of protein; but they are by no means of equal value in the easy diet: the former is free from protein waste and, to a certain extent, is protected from putrefaction; while the latter contains appreciable quantities of the extractives and purin bodies and is particularly susceptible to putrefaction.

Bearing in mind the fact that one article of food is not necessarily as good as another in the easy diet, although analysis may show it to contain apparently the same food principles, the problems of dietotherapy are seen to require for their solution a knowledge of the composition and qualities of the various articles of food and the physiological and pathological reactions which they excite after ingestion.

For the selection of protein-containing articles of food for the easy diet, a simple and useful criterion is found in the way the articles spoil. Practically all protein-containing articles of food, when they spoil, either turn sour or putrify. Bread, cereals, fruits, green vegetables, roots, and milk sour, while animal flesh and eggs putrify. The line of cleavage seems to run strictly between the animal and vegetable kingdoms until we come to milk, which alone among protein-containing foodstuffs regularly sours when it spoils. The souring of these articles, which is usually caused by the lactic acid fermentation of the carbohydrate which they contain, tends to inhibit the activity of the putrifactive bacteria, which in general are most active in an alkaline medium. The practical bearing of these facts on the easy diet becomes apparent when we remember that the split protein products which result from the putrifaction of protein are sometimes toxic and always burdensome to the organism. They also point to milk as the ideal source of protein in the easy diet. Nature knew what she was about when she invented milk for the easy diet of infants; and we can profit by the lesson suggested.

The easy diet, broadly considered, is seen to be lactovegetarian or approximately lactovegeterian. But, in so characterizing it, I must warn against being misled by a name. Any lactovegetarian or approximately lactovegetarian diet is not necessarily an easy one. The various articles of vegetable origin, as well as the milk preparations, in order to be acceptable in the easy diet, must be selected with due regard to their composition and qualities and the general reactions which take place between them and the organism, as well as the special reactions which belong to the particular case. Cane sugar, for example, is a hard food, and finds little place in the easy diet. Mushrooms and ripe peas and beans are vegetables of particularly bad repute as regards the easy diet.

In connection with the easy diet the matter of idiosyncrasies and special sensitizations come up. Not only articles of general poor esteem in the easy diet, such as the various flesh foods and eggs, produce these metabolic disturbances, but also articles which occupy a high place among easy foods, such as cheese, milk, and oranges, may produce them. Fortunately these idiosyncrasies and special sensitizations are much less common in the case of the recognized easy foods, excepting possibly cheese of the rennet made types (not the sour-milk cheese), than in the case of flesh and eggs, which are recognized as hard foods. The idiosyncrasy in regard to milk is sometimes a psychic one, but often it is merely a difficulty of digestion which can be overcome by modifying the milk so as to prevent its rapid curdling in large masses in the stomach. Simple likes and dislikes, personal prejudices and whims, and dietetic habits must not be confounded with idiosyncrasies and sensitizations. Here I would like to state that people can easily be taught to eat and like the right things. Eating is largely from habit.

Temporary starvation of various degrees is a recognized principle of dietotherapy, but it is important not to overdo it. Its successful use in the treatment of diabetes is one of the triumphs of dietotherapy. It is of great value in nitrogenous metabolic insufficiency, and the absolute exclusion of protein from the diet for one day in each week may be of great benefit in the treatment of chronic

Bright's disease. In the treatment of obesity partial starvation of fuel is the essential procedure. In some conditions of edema reduction of the sodium chloride intake to an amount much below the ordinary ration may prove beneficial; and in some conditions restriction of water is called for.

In acute infectious diseases the organism may be so disturbed that it cannot easily prepare and utilize an adequate amount of ingested food, finding it more convenient to utilize the reserve food stored in the tissues; and other reasons may exist for putting only small amounts of food into the alimentary tract; and in these diseases, which are of short duration, it is generally advisable to give scanty rations. But in infectious diseases of long duration, such as typhoid fever, in which the food reserves are exhausted and wasting of the tissues takes place, it may be highly desirable to push nutrition; and this can be done by suralimentation with carefully selected easy articles of food.

The rationale of suralimentation is suggested by the fact that the tissues can with increased facility get their requisite nutriment if the blood stream contains more than the quantity of food barely sufficient for their needs; and the further fact that restoration of the reserves of food stored in the body makes for recovery of the normal health balance.

A general principle of dietetics which is important but not paramount in the dietetics of disease, is the principle of palatability. Nature made food taste good so that people would be sure to eat it. There is no doubt that a good appetite and variety and palatability of the food make for improved digestion if not nutrition. The all around wise Shakespeare says, "digestion waits on appetite and health on both." But in dietotherapy it often happens that palatability and variety have to be subordinated to higher considerations.

The practical applications of dietotherapy are made in accordance with the general principles to which I have briefly alluded, viz., the principles of adequate nutrition and the easy diet, which are of universal application, and the principles of temporary starvation and suralimentation, which are of limited application; and also in accordance with the special indications which arise from local conditions in particular organs and apparatuses, from disturbances of the organism by general infections and toxemias, from metabolic insufficiencies and perversions, and from idiosyncrasies and special sensitizations. In a paper of this character I cannot, even in the most cursory manner, attempt any systematic review of the practical applications of dietotherapy; I can only give some disjointed and fragmentary remarks on a few topics selected at random.

By rectal alimentation it is often possible to maintain, not adequate, but partial nutrition to an extent sufficient to tide over an emergency; but the food introduced must be in a condition ready for immediate absorption, because the colon has not been proved to possess digestive capacity. The raw egg and milk enema, which is still recommended in the text books, is futile or worse. Water, salts, and vitamines can be given in their natural state. Carbohydrate can be supplied in the form of dextrose. Protein must be thoroughly predigested; that is, to the stage of amino acids, before it can be used. Fat cannot be used at all with advantage. The following is a list of articles which are available for rectal alimentation: Skimmed milk, which has been peptonized and pancreatized for several hours, so that its protein is reduced to amino acids; dextrose, which is a commercial product; strained orange juice or strained juice of fresh vegetables; sodium chloride, sodium bicarbonate and water. I have found it possible with these articles to supply a daily ration of 20 grams of protein, presumably in the form of the required amino acids, utilizable fuel of the value of 700 calories, salts and vitamines in fair quantity and variety, and water to the extent of 2,000 c.c.

In the medical treatment of gastric ulcer a diet is called for which excites as little as possible gastric peristalsis and the secretion of the hydrochloric acid, and which leaves the stomach quickly. A diet of modified milk, cereal gruels, and strained fruit juices, given in small quantities at frequent intervals, would seem best to meet these requirements. With improvement in the gastric condition, the diet can be enlarged, but mostly in the line of cereals, easily digested vegetables, and milk products. Eggs may be given cautiously, but animal flesh should be withheld until convalescence is well established and then given only in small quantity. In cases with recent hemorrhage, pain, or severe dyspeptic symptoms, it is advisable to begin with three or four days of rectal feeding; and in cases with severe hemorrhage the rectal feeding may require to be kept up for a much longer time. I have kept it up in such a case for twenty-four days with a successful outcome.

In chronic gastritis the indicated diet is very similar to that in gastric ulcer.

In acute diarrhea, which is usually a constructive process on the part of nature, at least at first, the diet should be restricted to water and salts, or the same with cereal decoctions, gruels, and porridges. Until improvement has appeared, all forms of animal food, even milk in some cases, should be avoided. The balance of power among the intestinal bacteria has been disturbed in acute diarrhea, and the safest pabulum to put into the bowel would seem to be a cereal preparation, which favors particularly the growth of the lactic acid-producing bacteria, which are preeminently the friends of man among the microbic inhabitants of the alimentary tract, although in excess they may become a nuisance; and this leads me to refer to the danger of over-colonization of the intestine with lactic acid bacteria, which can follow from too prolonged use of cultures of those bacteria.

In chronic constipation, chronic colitis, and all forms of chronic disease which produce an unhealthy condition of the intestinal mucosa or stasis of bowel contents, the indication for a non-putrifactive diet is present, that is, for a diet which tends to inhibit the activity of the saprophytic or putrifactive bacteria, in the alimentary tract. Without dwelling on this interesting subject, I will call attention to the fact that for practical purposes the non-putrifactive diet may be considered as lactovegetarian, that is, as composed of articles from the vegetable kingdom with the addition of milk—articles which sour when they spoil instead

of putrifying. But in many cases of chronic constipation and chronic disease of the intestine it is possible, without seriously impairing the non-putrifactive character of the diet, to include in it small quantities of flesh or eggs. In chronic constipation the diet should contain abundant cereals and green vegetables and fruits, which supply nature's laxatives, viz., insoluble cellulose and the laxative principles of fruit.

Chronic intestinal toxemia, particularly chronic poisoning by fragments of the protein molecule which are split off in the intestines by bacteria, and which are in excess relative to the toxicolytic power of the liver and tissues, or to which the body has become unduly sensitized, occupies an extensive place in medicine, and is best treated by diet on the lines above laid down. I will not go into this far-reaching subject more than to say that it is always safe to assume its presence in chronic degenerative conditions and metabolic insufficiency. A non-putrifactive diet, more or less rigid, cannot do harm in any condition, regularly does some good, and often produces remarkably beneficial results.

The acute febrile diseases, that is the acute infections, with specific toxemic depression of tissue metabolism and functional performance, regularly call for a very easy diet, and usually, when the disease is of short duration, for a comparatively scanty one. In most of the acute febrile diseases milk, variously modified, cereal gruels, strained fruit juices, alkaline salts to combat the tendency to acidosis inherent in fever, and water make up the list of preferred foodstuffs. In some of these diseases special dietetic indications appear; as in pneumonia, where the indication is for a diet which is restricted in quantity, safeguards as far as possible from intestinal toxemia and digestive disturbances, and supplies an extra amount of calcium; a diet, indeed, which makes it possible to avoid inducing artificial evacuations of the bowels during the active period of the disease, except in extraordinary conditions: extreme conservatism in the use of cathartics is a cardinal feature of the plan of treating pneumonia which I have been advocating for more than six years.

In acute febrile diseases of long duration, and notably in typhoid fever, a certain amount of suralimentation is called for in order to support the body against excessive wasting of its tissues. If the patient gets 75 grams of protein and 2,200 calories the indication for suralimentation may be considered as approximately met. Often patients cannot take as much as this.

In this connection I would like to say a word in condemnation of the use of animal broths and eggs in fevers. They are not easy but hard foods, being favorable culture media for bacteria of the more undesirable classes. Broths are possibly less objectionable than eggs, being quickly absorbed, and having the advantage of being tasty and of exciting the secretion of gastric juice; but they are practically without food value, and are burdensome to the organism, being little more than solutions of protein waste (meat extractives, purin bodies). Eggs have a positive food value and are free from waste proteins, but, as has been said, they are favorable culture media for undesirable bacteria; and in the raw state, in which they are so often given, they are objectionable for special reasons, particularly as regards their albumin. Raw egg albumin is not well acted on by the gastric juice; it slips quickly out of the stomach into the intestine in an undigested state, and to a certain extent it may be directly absorbed, producing reactions of a more or less anaphylactic character. The popular egg albumin water can be omitted from the invalid dietary with advantage.

In diseases of the heart the dietetic indications have to do largely with conditions of myocardial irritability and passive congestion. In conditions of lost or fragile compensation, the rule is to give small meals, frequently repeated; and with severe loss of compensation it may be necessary to make the diet extremely easy; and when there is edema, it may be necessary to restrict the amount of fluid. The Carel diet, which consists of small quantities of milk, no doubt owes part of its success to its non-putrefactive character. A dry diet, so called, should not usually supply less than 1,000 c.c. of fluid daily. Whenever possible it is desirable that the diet in heart diseases be fairly liberal, so as to insure adequate nutrition of the heart muscle.

In cardiovascular-renal disease regulation of the diet is of prime importance, and it is among the greater satisfactions of the practice of medicine to watch the improvement which so often follows the taking of a suitable diet in these conditions. In the early high-tension cases reduction of the blood pressure nearly to normal may often be brought about by this means; and in conditions with persistent high blood pressure generally diet is the best and usually the only means that should be employed to reduce the pressure, with the addition, perhaps, of rest. Elevation of blood pressure is a compensatory procedure, and high pressure should not be directly reduced except in extraordinary conditions, when its continuance at the high point threatens serious acute damage to body structures. The diet in this condition should be the easy one already alluded to. In cases of only moderate severity, flesh or eggs in small quantity may be allowed two to four times a week, rarely more often. Bacon, which contains but little flesh, and is extremely tasty, can often be allowed in small quantity, and serves to relieve the monotony of the lactovegetarian diet, especially for those who have been long habituated to the eating of much flesh. It is interesting to note, however, that patients with this condition soon become used to the meatless, sweetless diet, and in a large proportion of cases prefer it to their old diet; and they may tell you that their sense of taste has become more keen, and that their stools are smaller, although their present diet contains more insoluble residue than did their former diet.

An important point in this connection is the employment of the easy diet as a prophylactic of cardiovascular-renal disease. If those people whose apparent constitution, or family history, or ways of life, or present or past diseases suggest the early development of this disease, will adopt this diet, they can to a certain extent safeguard themselves from it; at least, they can delay its development. It is reasonable to expect that in the medicine of the future, which will be largely preventive, this phase of prophylaxis will receive deserved attention.

Nitrogenous metabolic insufficiency is mixed up more or less in all metabolic insufficiencies, but it seems to predominate in the pathological complex of which gout, gravel, migraine, and sometimes asthma appear to be manifestations; and one phase of this insufficiency is inability to get rid of the nitrogenous waste product, uric acid, with normal facility. No doubt other faults of metabolism enter into the case, including, it seems probable, an undue tendency to loss of the alkaline reserves of the body—a weakness in the direction of acidosis. The indicated diet is obviously lactovegetarian, with abundant fruits and green vegetables to insure the alkaline reserves, and abundant water, and with perhaps an occasional day of protein starvation.

Concerning the diet in diabetes mellitus, I will only say that the temporary starvation of protein and fat, as well as of carbohydrate, has been established beyond dispute as a safe and reliable procedure; but dazzled by the success of this procedure in clearing the urine of sugar one must not be tempted to carry it too far; and in many cases, especially among the elderly, it is often not advisable to try to make the urine entirely sugar free; and also in the types of the diseases occurring after middle life, in which nitrogenous metabolic insufficiency is more or less mixed up, regulation of the diet which takes into account the coexisting nitrogenous metabolic insufficiency usually results in an easier establishment of carbohydrate tolerance than one which fails to do so.

In obesity it is not usually desirable to reduce the weight by more than two pounds weekly, which would be accomplished by the combustion of about four and a half ounces of body fat daily. If oxidation in the body always went on at a uniform rate, which does not seem to be the case, due presumably to endocrine dyscrasias, that reduction would be brought about by a diet which supplied fuel less in value by 1,000 calories than the minimum caloric requirement for maintaining the existing weight. A convenient practical rule is to begin with a diet of 1,100 to 1,200 calories. Advantage may be obtained if the anti-obesity diet is also an easy one. Caution should be observed in reducing the weight of those who are old or diseased; but benefit is often obtained in cases of chronic myocardial degeneration in the obese by a reduction in weight.

In acidosis from any cause, alkaline salts and carbohydrate are called for in the diet, and fats are contraindicated. In cases with persistent vomiting rectal feeding is necessary, with dextrose to the extent of six ounces daily, and sodium bicarbonate to the extent of six or eight drams daily.

In tuberculosis moderate suralimentation is usually indicated, but the excess food should be easy. The days of stuffing with great quantities of raw eggs are passing or passed. Milk should constitute a large element of the diet, and patients in the active stage who are able to take it, should receive two or three pints of milk daily in addition to their regular rations, which should ordinarily include a moderate amount of flesh and eggs. Full rations of vitamines are particularly desirable.

Some cases of neurasthenia are benefited by a diet which is liberal in quantity and quality; but others, especially in older people, often do better on a more or less strict nonputrefactive diet.

In concluding these remarks, which have covered a wide range of topics without dealing fully with any of them, I would like to refer again for emphasis to a few of the points touched on.

The principle of adequate nutrition is of fundamental importance and universal application in the dietetics both of health and disease. It is often violated, most commonly by failure to substitute equivalent necessary food for that which has been regulated out of the diet.

The principle of the easy diet is of universal application and paramount importance in dietotherapy; in fact, dietotherapy consists essentially in the application of this principle to particular cases. The easy diet has to do not only with the quantity of the food, but also with its quality; and requires knowledge of the composition and properties of the different foodstuffs, and of the physiological and pathological reactions which they excite in the organism after ingestion. Two points of special importance in the easy diet, around which cluster many practical considerations, are bacterial activity in the alimentary tract and acidosis. The non-putrefactive diet can be employed to change the character of the intestinal flora from the more malign to the more benign types; and the diet can be so arranged that the articles which contain an excess of base-forming over acid-forming elements will predominate sufficiently to safeguard the alkaline reserves of the body. The basic formula of the easy diet is a lactovegetarian one, but modifications of that formula may be allowable and desirable in particular cases. Animal flesh is often poison, but often also medicine, and always food; and while intemperance in eating has been the cause of a large amount of disease and shortening of human life (a much larger amount than intemperance in drinking of alcohol), a hue and cry against it is to be deprecated. In many cases of chronic disease which call for an easy diet, small amounts of flesh can usually be allowed with advantage, or at least without particular harm.

Temporary starvation and suralimentation are of great value in dietotherapy when used strictly according to indications, but are capable of much harm if overdone. Palatability and variety of food should not be neglected, but should be sought within the limits set by the more important dietotherapeutic considerations.

Hippocrates says: "Life is short, the art long; the occasion fleeting; experience fallacious and judgment difficult." Dietotherapy is yet far from being reduced to a complete system of definite formulas. Opinion still prevails to a considerable extent, and inevitably so. But facts are steadily accumulating and principles are beginning to appear, and we may consider that at least the foundations of scientific dietotherapy have been laid.

1218 Pacific Street.

The Wassermann Reaction in Malaria.—De Jong had an excellent opportunity to determine the connection between malaria and a positive Wassermann in the evacuation of 300 troops. In every paludic examined between crises there was a negative reaction, save for patients who were known to be syphilitic; but in the midst of an access the reaction was always positive. —*Journal de médecine et de chirurgie pratiques.*

ON FOCAL INFECTION AS A CAUSE OF PAINFUL HEEL.

BY SIGMUND EPSTEIN, M.D.,

NEW YORK.

ACTING CHIEF OF ORTHOPEDIC CLINIC, MT. SINAI HOSPITAL DISPENSARY; ORTHOPEDIC CHIEF, BRONX DISPENSARY.

IN civil practice, it is not unusual for an ordinary podalgia case to pass muster for flat-foot or goutiness; there is a certain amount of disability on walking, but on casual examination there is little to be learned from the symptoms.

In the concentration camps, however, many cases of exostosis and periostitis of the heel have been unearthed by the orthopedic inspectors, and prompt action has been taken to safeguard the recruit. Unless the soldier has a painless pair of feet, he will be of no use in marching or fighting. Many such feet will require treatment, result in allotment to secondary tasks, or the granting of a surgeon's certificate of disability. The free use of our splendid army *x*-ray equipment is a measure of great military efficiency in aching, tender heels. The orthopedic instruction camps pay particular attention to the subject of calcaneal spurs, and their importance is duly recognized. If the original focus can be detected and cleared up, a useful soldier and another man will accrue to our fighting forces.

I will discuss here three causes of painful heel: those due to tonsillar infection, those secondary to oral infection, and the gonorrheal heel.

I have seen many cases of arthritis and painful feet whose origin was discovered to be tonsillar; the following case is one of uncomplicated periostitis of the heels, that is rather unusual.

CASE I.—A young man of twenty-three was sent to me by his physician, complaining bitterly of tender heels. The venereal history was negative, as was the previous history. He had had a slight attack of tonsillitis several days before starting on a sea voyage to the south. On the fourth day out he was seized with a sudden swelling of the right ankle and heel, with redness and heat. The ship surgeon painted this with iodine, with little result. A week later the left heel became tender, without swelling. The right heel became free from pain at the end of three weeks and he was able to leave the bed, but an excruciating tenderness of each heel practically prevented him from walking for eleven months. During this time two thoroughly competent orthopedists etherized him on different occasions, stretched his feet, and applied corrective plaster of paris splints. He diligently sought relief from pain, was given shoes and plates, and further "tortured." At the end of eleven months I found marked tenderness on the inferior and outer surfaces of the os calcis in each foot. He walked so as to throw the minimum amount of weight on the heels. The *x*-ray showed extreme thickening of the periosteum of of the under surface, and when this was demonstrated he immediately agreed to operation. A week later I curetted the much thickened periosteum through a mid-heel incision and chipped off the right peroneal tubercle. Sixteen days later he went to work on heels that were free from pain, and this has never returned, in spite of arduous work in the army in the Philippines. No supports of any kind have been worn since.

There have been many cases of arthritis and painful feet which gave a history of previous tonsillitis. Brilliant results from tonsillectomy can be expected in cases like the following:

CASE II.—A salesman, twenty-five years old, was sent to me by his family doctor. He had had a gonorrhea seven years ago, and two attacks of quinsy in the past two months. For four weeks there had been much articular and muscular pain in many parts of the body; the feet were very painful, he had to creep to the street car. There was demonstrable tenderness under the heels, the fifth metatarsals, and the joints of the great toes. Tonsillectomy was not carried out until the patient had endured great discomfort for another six weeks; then the infection and its attendant symptoms cleared up permanently within forty-eight hours.

But the tonsil, it must be remembered, is a clearing station for mouth infections, and it is manifest that the tonsillar attacks are often due to dental troubles; hence some arthritides are not cured until appropriate extraction is carried out, or until some pyorrheal pockets are cleared up.

So much has been written on the subject of arthritis, rheumatism, and osteoarthritis from dental lesions, that anything added to what has been contributed by Hunter, Rosenow, Billings, Hartzell, many bacteriologists, dentists, etc., would be superfluous. The dental cases can be exceedingly acute and destructive. The more chronic dental cases are seen in middle aged or elderly patients, and osseous changes can be demonstrated around the joints. Total ankylosis is not common.

I will offer a few impressions of my study of many cases seen in private and clinical practice:

1. I believe that the results of extraction of teeth are more brilliant than those of root-amputation.

2. Often the beneficial results of removal of septic bridges, and of forgotten or buried septic roots can be felt within a day, after the eradication.

3. Do not expect this to happen where there have been marked bony changes around the margins of joints, such as the *x*-ray shows in the form of osteophytes of greater or lesser size.

4. The results of extraction of septic dental foci are more favorable in younger patients, especially where the symptoms are polyarticular or muscular.

5. Physicians should be able to recognize pyorrhea, neglected or infected teeth, teeth of dark appearance, gold and porcelain crowns. Sinuses, especially small ones, should excite suspicion, and should be followed up roentgenographically. In this day and age of literature on focal infections and their diligent tracing, it is to be wondered that cases still escape the vigilance of the most careful medical attendants. Especially when the patient is a practising physician is the loss of time as well as the extension of the disease process more lamentable:

CASE III.—A physician, forty-nine years old, had been ill in bed for ten weeks with a vicious infectious osteoarthritis of both metatarsophalangeal big-toe joints. The onset was with grip and tonsillitis, which lasted a week. His right big toe swelled on the seventh day, the left on the tenth day. Each joint was distended, red, and intensely painful night and day; the temperature was usually 102° during the first fortnight. He was in bed six weeks, on crutches four more; then he came to New York. He had received all the known antigout remedies from his fellow townsmen, all the diagnoses having agreed on gout. He was sent to a dentist and to me by a consultant of great skill, who found and ordered the extraction of a wobbly, infected, last molar tooth. This tooth presented an almost imperceptible little sinus, that had escaped the searching inspection of all but the last consultant. The tooth was immediately extracted and the feet were placed

in plaster of paris bandages. The doctor at once experienced much relief from his grinding pain and disability. Strength quickly returned and ten days sufficed for practical resolution. Both big toes showed in the radiograph the following changes in the metatarsophalangeal joints; cartilage destruction, subperiosteal atrophy, and small osteophytes. These joints have remained partially ankylosed; the patient is sorry that that focal infection was not suspected sooner. He resumed practice in three months.

The gonorrheal origin of periostitis of the heels was convincingly demonstrated by W. S. Baer in 1905, who then described six cases. Since then many papers have described this interesting condition. In many discussions with New York surgeons on the subject, how difficult it was at first to make them believe the relation of cause and effect!

Thomas Hunter's writings on the cases of rheumatism and anemia from foul dental and oral conditions have changed the opinions and the professional attitude very markedly, however, in the last three years, and focal infection symposia, being profitable, are attentively listened to. Some orthopedists look at teeth and tonsils before the patient's shoes are off. Many teeth are needlessly sacrificed in haste, the action only to be repented at leisure. More careful examining is being done, and medical minds are no longer so narrow that all aching heels are doomed to plate wearing.

A series of 14 recent office records of gonorrheal heels have led to certain deductions. Most of the cases studied have been observed for long periods and the results can be definitely stated. They all were males except one, and all under 40 years of age. One had undergone a seminal vesiculotomy, and could not walk until curettage of the heels was done; six were operated on and returned promptly to work. The heels were curetted only when an extremely tender point or an exostosis was demonstrable. The *x*-ray is here indispensable. In my experience, cultures of most of the scrapings have been returned negative, because of the short life of the gonococcus in the periosteum. The usual result of a calcaneal metastasis having its origin in prostate or urethra, is a hypertrophic periostitis. No pus is formed, and the organism is not long viable, even though it is immensely troublesome.

Recurrences of gonarthritis in other localities followed the usual percentages. Four suffered from it as a complication and were eventually cured by careful and persistent urological attendance. The others were treated by efficient local treatment to urethra and to feet.

Arthritides and osteoarthritides are common from dental infection, but distinct calcaneal periostitis has not been, in my observation, so common. Therefore the following cases are of interest demonstrating a cure of painful heels after extraction of a tooth.

CASE V.—A civil engineer, thirty-seven years old, venereal history negative. Heels began to hurt two weeks after a tonsillitis and the pain continued for six months. There was little to be detected except tenderness under each os calcis. No deformity; *x*-ray negative, except the merest trace of thickening of the calcaneal periosteum. A small sinus above the second upper molar was found and, after months of delay and discomfort in the heels, it was extracted. The pain was promptly relieved.

CASE VI.—Cloak manufacturer, thirty years old, who gave a history of pharyngitis and tonsillitis twice during January. In April there was noticed a gradually increasing lumbar backache, with painful swelling and aching of the heels and soles. There was no fever nor any other evidence of general infection. He had no comfort from shoes and orthopedic treatment; plates and medicine, prescribed by two competent orthopedists visited, were of no use. He could not sit or lie down in comfort, and walking was painful. Physical examination disclosed a suspicious left last molar (crowned) and dusky tonsils. The spinous processes in the dorsolumbar region were tender; likewise the heels, especially the under surfaces. The right metatarsal arch was very tender and some swelling was noticeable. Diagnosis: Arthritis, with periostitis of the under surface of the right heel, verified by an *x*-ray examination. The *x*-ray also demonstrated that the third left upper molar (crowned) was diseased. When a bridge attached to this tooth was removed the root was found abscessed. After appropriate dental treatment all pain disappeared, showing a remarkably prompt response to the removal of the source of focal infection. His tonsils, as far as I know, have not been excised, and he has remained well.

15 WEST FORTY-FOURTH STREET.

FOREIGN BODY IN THE UTERINE CERVIX.

BY LUCIUS FELIX HERZ, PH.B., M.D.,

NEW YORK.

FIRST LIEUTENANT U. S. O. R. CORPS; ASSISTANT SURGEON, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

A COLORED woman recently came into my office complaining that while taking a douche, the douche tip had become caught in her cervix and that she was not able to remove it.

The patient was placed upon the table and a bivalve speculum inserted, and it was found that a hard rubber very small rectal tip was deeply imbedded in the cervical canal, so that it was just barely possible to see it. The axis of the cervix was directed posteriorly and it was hence difficult to keep the cervix within the field of operation. Also the patient was so hysterical and screamed so easily that it was almost impossible to keep the speculum in place. However, after a persistent effort I managed to keep the cervix in sight long enough to introduce a uterine dressing forceps in the direction of the foreign body, grasped the douche, or, rather, rectal tip, and removed same.

The patient claimed that this was the only douche tip she had had available, and that the current of the fluid carried it up into her cervical canal. At first we were inclined to doubt her story, as with four vaginal fornices to choose from, it would be by an extremely slim chance that the douche tip would ignore these and make a "bull's eye hit" directly into the cervix. The most logical deduction would appear to one to be that the patient had purposely introduced the douche tip into the cervix, either to produce dilatation or to self-administer an intrauterine douche with intent to produce abortion.

We were much surprised to find upon taking a complete history upon the patient that she had had a supravaginal hysterectomy performed a few months before, at Bellevue Hospital. Bimanual examination bore out her statement, and apparently both tubes and ovaries had been simultaneously removed.

Thus by a careful history and examination we have proven that it is possible for a douche tip to find its way directly into the cervical canal, in spite of all the other directions open to it.

AN OPEN SAFETY PIN SWALLOWED BY AN EIGHT-MONTHS-OLD CHILD, AND PASSED THROUGH THE RECTUM AFTER FOUR DAYS.

By SAMUEL WEISS, M.D.

NEW YORK

ATTENDING GASTRO-ENTEROLOGIST, PHILANTHROPIN HOSPITAL, FELLOW AMERICAN CONGRESS ON INTERNAL MEDICINE.

THE presentation of this case is of interest because of its favorable termination without operative interference, and also because of a hasty and erroneous diagnosis due to faulty interpretation of the *x*-ray evidence.

R. N., eight months of age, and the only child, swallowed a small safety pin which was open. The mother became alarmed and ran to a physician who advised her to have an *x*-ray taken. Following this procedure the child was referred to a nose and throat institution, where after twenty-four hours time the mother was told that she must take the child to another hospital as the case could not be handled there.

Directly from the hospital she brought the child to my office, and after fluoroscoping the child and locating the pin with its point down, a little below and to the right of the xiphoid cartilage, the little patient was placed on her abdomen and an *x*-ray plate taken. (Fig. 1.) Following this the child was given a small quantity of a barium-buttermilk mixture and this time *x*-rayed in the upright position. (Fig. 2.) After developing the plates and examining them I concluded that the pin was in the region of the duodenum.

FIG. 1

FIG. 2.

FIG. 3.

The patient was admitted to the Philanthropin Hospital, on Dr. Cronson's service, who after viewing the *x*-ray plates decided to wait for further developments. Upon his advice, twenty-four hours later the child was again *x*-rayed and this time the pin was located in the cecal region and most of the barium which was administered the previous day was in the rectal ampulla. (Fig. 3.) As the child had no elevation of temperature and was nursing and sleeping without being peevish the operation was deferred with the intention of *x*-raying the child again the following day. During the night the child was restless and cried but fell asleep again; another plate was to be taken and if the pin was in the same place the patient was to be operated on. However, before another *x*-ray was taken, the nurse reported that the child had passed the pin which was imbedded in a hard fecal mass.

Credit is due to Dr. Cronson for his judgment and conservatism, which prevented unnecessary mutilation of the little patient.

616 MADISON AVE.

Morbid Manifestations of Rapid Growth.—Guelpa enumerates weakness, neuralgias, migraine, anemia, pallor, dysmenorrhea, indisposition toward any kind of exertion. The rationale is that these subjects with rapid or abnormal growth tend to develop gastrointestinal intoxication, while a second factor is overexertion. This reasoning is based on the fact that such cases improve on a treatment based on disintoxication and rest. —*La Presse Médicale.*

Medical and Surgical Lessons of the War.

EXTRACTION OF WAR PROJECTILES FROM THE THORAX.

By Dr. RENE LE FORT
LILLE, FRANCE.

The primary treatment of chest wounds due to war projectiles has lost much of its direct practical interest since the armistice. Experience has shown the great improvement in the prognosis of thoracic wounds through active measures aiming at the direct treatment of the wound during the first few hours, namely, mechanical cleansing of the parts, hemostasis, and extraction of foreign bodies, just as in wounds of other regions. At the present day, the question most frequently confronting the surgeon is this: When a wounded soldier has carried a bullet or a shell splinter for several months, or even several years, in his chest, is its removal advisable or not? In order to answer this question one must be familiar with: (1) The subjective disturbances resulting from the presence of the projectile. (2) The dangers which its presence may involve. (3) The surgical possibilities of its extraction and the methods at the operator's disposal for

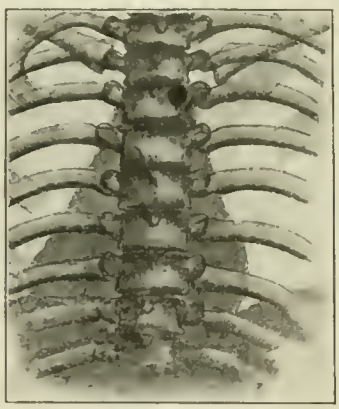

Fig. 1.—Shrapnel bullet on the anterior aspect of ascending aorta.

the performance of the operation. (4) The sequelæ of the operation.

I shall endeavor to answer these four questions on the basis of the results of my investigations and personal experience. Projectiles in the chest wall are only moderately interesting, and involve problems of merely secondary surgical importance, so that these will here be left out of consideration.

I. SUBJECTIVE DISTURBANCES RESULTING FROM THE PRESENCE OF AN INTRATHORACIC PROJECTILE.

These discomforts are variable. Some patients present symptoms relating to the special seat of the projectile—persistent cough, hiccough, vomiting, etc., caused by direct irritation of the phrenic or pneumogastric nerve. Such cases are exceptional. The predominating symptoms are: Deep-seated pain, which is rarely absent; impossibility of resting on the affected side, respiratory disturbance, sometimes reaching the point of dyspnea, and sometimes cardiac palpitation. Not infrequently there is a little bronchitis or emphysema; small recurrent hemoptyses are not uncommon, but the symptomatology often seems not well marked, which is misleading, for the clinical picture is dominated by a constant and serious symptom, which makes regular invalids

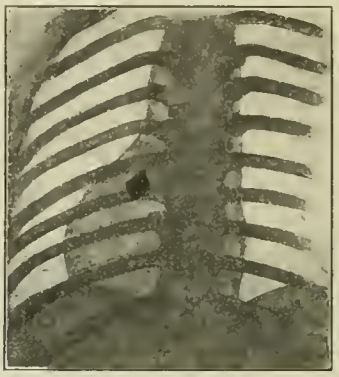

Fig. 2.—Three shell splinters (blended in a single picture) on the anterior wall of the left auricle.

of these carriers of intrathoracic projectiles, viz., dyspnea on exertion. This is borne out by the history of most of these patients, which never varies and can be briefly summarized as follows: X. received a bullet in the chest, is admitted to the hospital and a radiograph is taken; the bullet is at a distance from the surface, and the surgeon hesitates to extract it, so keeps the patient under observation. The condition improves, so that the bullet is left alone, and the patient is discharged on convalescent leave. As soon as he begins to work, he is attacked by dyspnea on exertion, together with pain, palpitation, sometimes coughing, and then he enters another hospital. Repeated radiography, renewed hesitation on the part of the surgeon, another period of observation followed by improvement; convalescence, renewed attempts to resume work; reappearance of the dyspnea, and repetition of the cycle. I have seen such patients who had passed through eight or ten hospitals without obtaining the slightest improvement in this condition.

The rule should therefore be to remove all intrathoracic projectiles, except very minute fragments.

II. DANGERS DUE TO THE PRESENCE OF INTRATHORACIC PROJECTILES.

The presence of a foreign body in contact with the large arteries of the mediastinum seems to expose these vessels to the risk of ulceration through the rhythmic friction of pulsation. Fearing this contingency, I have performed numerous extractions of projectiles in contact with the aorta, the pulmonary artery, and the large vessels of the hilus. Examination in situ of the macroscopical anatomical changes produced in the tissues, more particularly in the vascular walls, by the presence of a foreign body, permits the rather unexpected conclusion that the arteries effectually defend themselves, through a variety of procedures which it would take too long to describe here, but which will be found detailed in a paper presented to the Paris Académie de Médecine on June 11, 1918, and that a projectile does not erode or perforate a vessel unless the latter is unable to escape

from it. This unfavorable condition rarely exists, but was present in one of our patients whose aorta was compressed by the tip of a bullet the base of which rested on the spine; the vascular compression gave rise to a blowing sound which disappeared

Fig. 3.—German bullet in the posterior wall of the right ventricle. Complete cardiopericardial symphysis. Extraction of the projectiles shown in Figs. 1, 2, and 3 was followed by recovery.

after extraction of the projectile. The patient made such a good recovery that he became an aviator and subsequently lost his life in an air fight. Similar observations are rare, and inclosed projectiles hardly ever threaten large blood-vessels, but they are irritants which may sometimes become the starting point of infectious complications, the occurrence of which is favored by the vicinity of the bronchi, even in the case of very deeply situated projectiles.

The danger of sudden fatal embolisms in case of projectiles in the cavities of the heart is too obvious to require more than cursory mention. The fate of projectiles in the walls of the heart remains unknown.

III. POSSIBILITIES OF SURGICAL EXTRACTION, AND METHODS AT THE SURGEON'S DISPOSAL FOR THE PERFORMANCE OF THE OPERATION.

All intrathoracic projectiles can be extracted. One of my first interventions led me to assume the existence of a prohibited zone at the posterior portion of the left auricle, but this is not true. The entire lung, the entire mediastinum, the heart and its cavities can be freed from the projectiles which they contain. At the present writing, there are on record in France a certain number of cases of extraction of projectiles from the walls of the heart and a few of extraction of projectiles from the cavities of the right heart; as regards the cavities of the left heart, I know of no extractions other than those performed by myself. One of the latter was a case of shell splinter in the cavity of the left auricle; the patient was an aged man who died on the fourth day after a night disturbed by a Zeppelin air raid, during which he remained uncared for. The second case was one of the removal of a splinter from the cavity of the left ventricle; the patient was entirely cured.

The extraction of intrathoracic foreign bodies is not practicable without the observation of a certain number of definite rules:

A. All interventions for intrathoracic projectiles must be preceded by a complete radiological study on the part of the surgeon assisted by the radiographer.

Radioscopy furnishes more information than radiography, but neither of the two should be neglected.

Radiological examination supplies important data concerning: (*a*) The existence of a foreign body; (*b*) its anatomical localization; (*c*) its physiology, *i.e.* its movements; (*d*) its geometrical localization; (*e*) its nature and its qualities; (*f*) the condition of the surrounding parts and of the thoracic organs.

B. All operations must be safeguarded by the control of the screen. Radioscopic control is indispensable in the course of the operation. It may be utilized under various forms, according to circumstances:

(*a*) In case of simple interventions, such as the majority of extractions of pulmonary projectiles at a distance from the hilus, the radioscopic control can be advantageously provided by the operator himself, who does his work in red, blue, or violet light.

(*b*) In case of complicated major interventions in dangerous regions, it is indispensable for the surgeon to operate in full daylight. The intermittent control of the screen, although a useful method, is in this case inferior to the employment of the hood, if it is possible to entrust the latter to an experienced radiologist, and one willing to serve only as an assistant. Operative failures are almost exclusively the result of missing or insufficient radiological assistance. But the surgeon should never neglect the use of adjuvants which may prove extremely serviceable under certain conditions, such as a well-regulated compass, the finger-stall of La Baume-Pluvinel, the electrovibrator, the head-mirror.

(*c*) Resections of ribs and cartilages must be carefully avoided in all operations performed by the anterior or lateral routes. Resected ribs and cartilages do not regenerate or are replaced by ir-

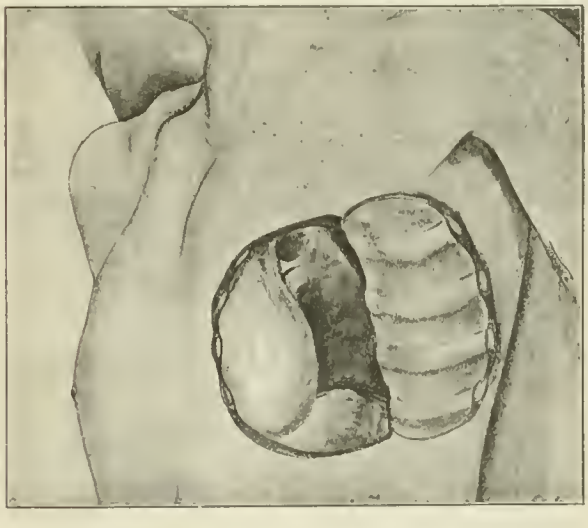

Fig. 4.—Costal flap involving the third, fourth, fifth, and sixth ribs; drawn by M. Macquet from nature during operation on case illustrated in Fig. 3. (*Revue de Chirurgie*, 1919.)

regular and ofter inconvenient bony patches. These new formations are sometimes observed after simple cartilaginous resections. Certain individuals who have undergone extensive resections of the ribs are thereby reduced to a state of real invalidism.

These general rules being understood, it is obvious that the technique of extraction cannot be uniform in all cases. The best technique is that which provides the maximum operative security while causing a minimum of destruction, and it varies with the seat and size of the projectiles, as well as the anticipated difficulties of the intervention. The methods of selection are the following:

1. Small and medium-sized projectiles in the pulmonary parenchyma at a distance from the region of the hilus and the mediastinum are to be treated by *extraction with forceps under the control of the screen*, according to the procedure of Petit de la Villéon. A skin incision a few millimeters in length is made, and through this opening a pair of long forceps whose jaws open only near the extremity of the instrument is introduced and is pushed through the tissues in the direction of the projectile, while the operator follows on the radioscopic screen all the movements of the forceps, of the projectiles, and of the patient.

This procedure has been severely criticised. The tearing out in the dark of an invisible pro-

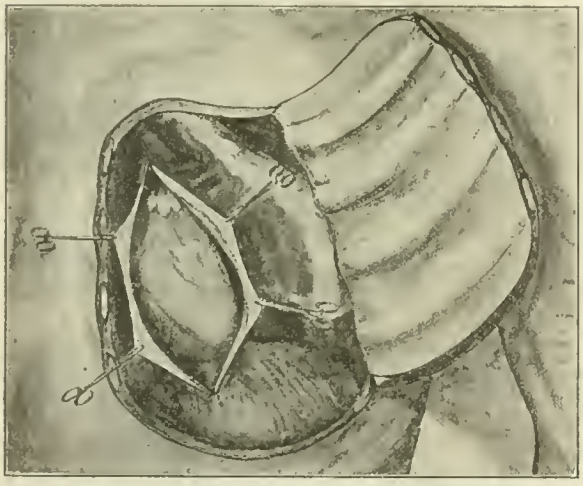

Fig. 5.—Avenue of access to the heart, the large bloodvessels, and the pericardial cavity, by the costal flap with external hinge, and incision of the pericardium in front of the left phrenic nerve. (*Revue de Chirurgie*, 1917.)

jectile, surrounded by unseen bloodvessels and tissue layers, is revolting to the surgical mind. The procedure is difficult and even after some practice often requires prolonged groping. The projectile escapes from the forceps and is pushed back into the dark recesses of the thorax where the presence of opaque bloody extravasates further diminishes visibility and interferes with the exploration. The results are excellent, however, and the immediate and permanent sequelæ are extraordinarily free from complication. After lengthy explorations with the forceps in the midst of the lung tissue, the patients may be seen walking about, without disturbance or reaction of any kind, forty-eight hours after the operation.

2. A few large and irregular shell splinters of large size, situated in the superficial layers of the lung, can be removed by means of Marion's procedure, namely, by pneumotomy, after fixation of the lung to the chest wall. This operation through a small opening can be done only in exceptional cases.

3. All projectiles of the dangerous regions of the mediastinum, all those of the hilus, the pericardium, the pulmonary ligament, must be operated on through a wide avenue of approach.

The fear of pneumothorax has long proved a stumbling block in the progress of intrathoracic surgery. Notwithstanding the efforts of Bazy, the majority of operators dreaded it prior to the war. However, pneumothorax is remarkably well tolerated when the myocardium is not seriously diseased. It is a not much more serious matter widely to open the pleura than to open the peritoneum. Flattening of the lung against the vertebral column, on opening the thorax, is a myth, and occurs only in the cadaver. Moreover, pleural adhesions are very common in thoracic injuries, and prevent the development of pneumothorax.

I have shown in a communication to the Paris Académie de Médecine, June 12, 1917, that an immediate wide opening of the pleura is better tolerated than and preferable to a narrow opening, and since 1916 (Académie de Médecine, November 28, 1916) I have advocated it as a route of access to the mediastinum, presenting conclusive facts in its favor. *The wide transpleural method*, recommended by Duval in the case of projectiles in the lung, is, therefore, the method of choice for the extraction of intrathoracic projectiles situated in dangerous regions, and it alone permits a clear insight into what is being done. From this point of view, the anterior or anterolateral route, is, in my opinion, immeasurably superior to the posterior route. (Fig. 4.) The classical idea of approaching the anterior mediastinum by the anterior route and the posterior mediastinum by the posterior route is actually based on an anatomical error. Almost the entire mediastinum is in the anterior half of the thorax, and the anterolateral wall is thin and flexible, whereas the posterior wall is thick and rigid. In a paper read before the Paris Académie de Médecine on February 11, 1919, I have given the statistics of my first hundred operative extractions of projectiles lodged in the mediastinum or its immediate vicinity. The posterior route yielded the enormous figure of 5 projectiles left behind in 15 interventions, equivalent to 33.3 per cent. The narrow transpleural route and the transsternal route yielded 6 failures among 28 interventions, equivalent to 21.4 per cent., whereas the wide transpleural route yielded 5 failures in 57 interventions, or 8.7 per cent. These statistics, which will be referred to again later on, concern especially the most improbable cases.

After employing a great variety of methods of wide transpleural access I have been led by experience to retain two which have proved entirely satisfactory.

(*a*) *The costal flap with external hinge of Delorme.* (Fig. 5.) The technique has been defined and improved by me in several publications. This flap is cut widely and regularly by dividing the costal cartilages and the intercostal spaces at equal distance from the bordering ribs (so as to permit the repair of the wall); it is then raised, guarding against fracture of the ribs either by simple elevation, if the flap can be extended very far outward, as is the case with the lower ribs, or by causing a greenstick fracture through strong but cautious

pressure, as can be done in the majority of youthful individuals, up to and even above thirty years of age.

This procedure provides the most light, permitting complete exploration of the entire thoracic cavity, from the clavicles as far as the diaphragm, and from the sternum to the vertebral column and the ribs behind. It facilitates all manipulations, the introduction of both hands and instruments into the interior of the thorax, and the direct inspection of the entire cavity. Very recently I succeeded without difficulty in obtaining hemostasis of the wounded azygos major vein behind the diaphragm, by means of an anterior flap.

(*b*) *Very wide intercostal incision associated with simple incision of the supra- or subjacent costal cartilages* (Le Fort). (Fig. 6.) As in the case of the flap with an external hinge of Delorme, the

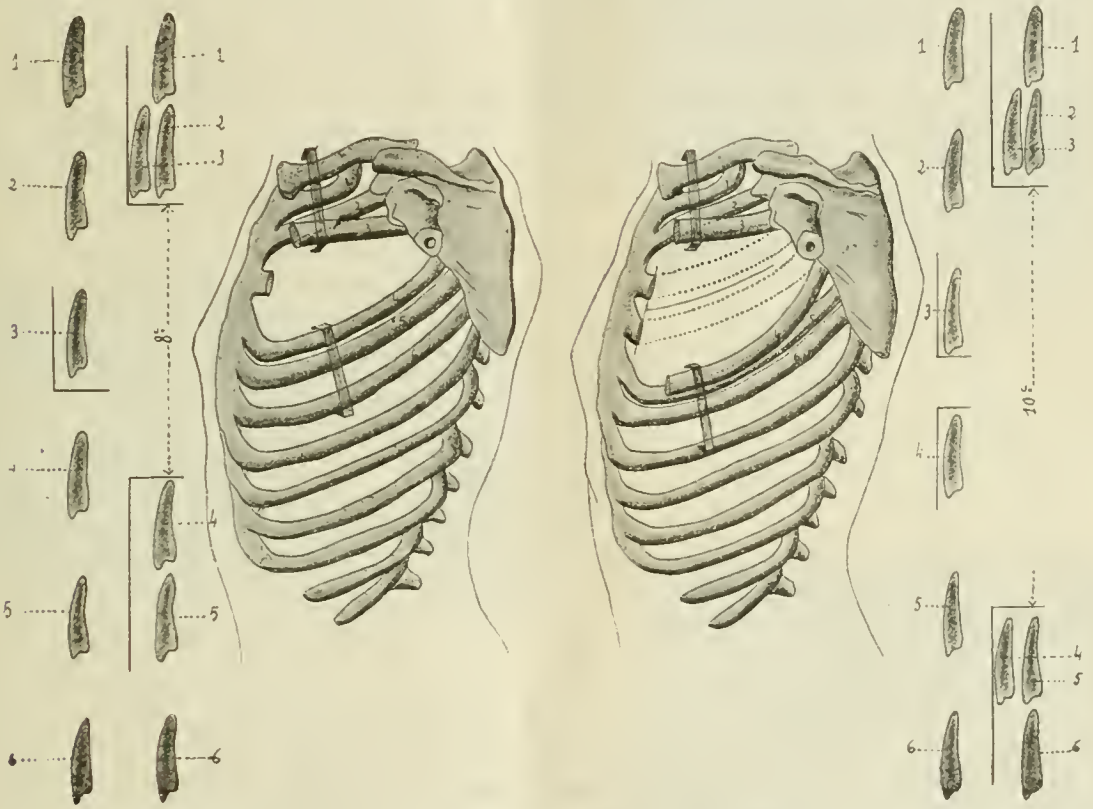

FIG. 6.—On the left, incision of the third intercostal space with division of the third costal cartilage, showing the result obtained by maximum separation of the ribs. Sectional and frontal view. On the right, the same with the addition of a division of the fourth costal cartilage. The two figures show the ribs, whose cartilages have been divided, overriding the neighboring ribs. (Le Fort, *Revue de Chirurgie*, 1917.)

procedure causes no mutilation of the thorax. The repair of the wall is easier and can be made even more accurately than after the Delorme flap, and the operation is perhaps even more free from danger. The procedure permits the breach in the chest wall to be made more or less extensive, according to the necessities of the case. A simple incision of one intercostal space permits separating the ribs by about 6 centimeters; division of the cartilage above or below permits of a separation of 8 centimeters; division of both cartilages together gives an opening of about 10 centimeters; and the supplementary division of another cartilage enables one to enlarge the separation to 12 centimeters. It is very advantageous always to make the incision in an intercostal space situated slightly below the level of the foreign body which is to be extracted. This way of proceeding involves a twofold advantage: on the one hand, the avenue of access supplied by the incision of an intercostal cartilage is so much the larger, the lower the intercostal space; on the other hand, the intercostal incision combined with incision of the costal cartilages above can be very easily transformed into a costal flap by simple section of a higher intercostal space.

These two procedures are sufficient in the vast majority of cases. In certain exceptional cases, however, special procedures are advantageously utilized. In a recently published book (*Les projectiles inclus dans le médiastin*, Paris, 1918) I have described a certain number of these, for the most part not previously published. I will here mention only the two following:

1. *The sternocleidocostal flap.* (Fig. 7.) This operation provides free access to the cervicomediastinal "crossroads" to the arch of the aorta, the origin of the carotids, the brachiocephalic trunks and the subclavian veins, the internal portion of the apex of the lung, and the entire half of the superior mediastinum without sacrificing the clavicles, without opening the sternocostoclavicular articulations, without damaging any organ, any vessel, nerve, or important muscle. It consists in turning upward and outward a flap which comprises the clavicle, the first rib, and the upper outer segment of the sternal manubrium where these bones are inserted.

2. *Median incision of the sternum, the pericardium, and the diaphragm,* or Duval's method, provides free access to the heart, and is recommended for certain operations upon the right heart. Sometimes it may be desirable to add to the flap with an external hinge, a small sternal flap with an internal hinge, etc.

The detail of these procedures does not really make much difference. The indispensable requirements are to provide all the necessary light for the operative intervention by means of a large gap, which can be further enlarged should an unexpected necessity arise, and to avoid all permanent mutilations, so as to permit an essential repair of the thoracic wall after the completion of the operation.

Discovery and extraction of the projectile. On opening the thorax, pleural adhesions are frequently met with, sometimes a real symphysis. The detachment of these adhesions is readily accomplished by means of compresses, like the detachment of a hernial sac, with sufficient completeness for the performance of the operation. Adherent lungs are lungs which collapse completely after detachment, and which it is advisable not to separate entirely from the thoracic wall. It is preferable to leave a zone of adhesions above and below, in order to prevent a complete collapse of the diseased lung, so different from the always very expansible free lung.

The projectiles are free, or adherent to the interior of a sheath of variable thickness. It is noteworthy that the adhesion of a projectile to the neighboring tissues may be considerable, and that a very painstaking separation, effected most patiently, millimeter by millimeter, is sometimes required, necessitating prolonged manipulations for the avoidance of grave accidents. This refers especially to projectiles imbedded in the walls of the heart. The thoracic organs in general possess a remarkable tolerance for investigations and operations serving for the liberation of projectiles.

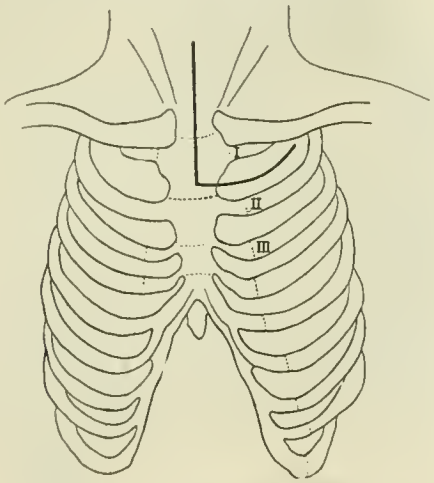

FIG. 7.—Line of incision for the sternocleidocostal flap. Le Fort. (*Presse Médicale*, 1918.)

The aorta conveys to the finger the feel of a bicycle tire. The pulmonary artery is strong and resistant. The phrenic and the pneumogastric nerves are easily recognized; the trachea and the large bronchi are plainly perceptible to the finger. The lung is soft, and can be displaced in all directions without inconvenience. The heart is a viscus whose hardness and strength are truly remarkable. One can move it about and raise it without fear. Pressure on the ventricles accelerates its action, while pressure on the auricles slows it. The cardiac walls may be pricked, pinched, or incised without a *very prolonged* modification of the rhythm; the auricles may be pinched or pulled, but compression of the communicating canal of the auricle and auricular appendage causes instantaneous arrest of the heart. In a general way, all manipulations may be cautiously attempted. When arrest or grave changes in the rhythm of the heart supervene they cease almost immediately after the manipulation which has caused them.

This extreme tolerance permits the performance of apparently most dangerous operations. My personal observations include the extraction of eleven projectiles from the heart, of foreign bodies attached to the walls of the aorta, the pulmonary artery, the vena cava, the esophagus, etc. Extractions have been performed through complicated routes: a bullet in the right ventricle of a patient with cardiac adhesions had to be approached from behind the pericardium; in other cases projectiles were removed by the bitranspericardial route, etc.

IV. SEQUELÆ OF THE OPERATION.

The operative results are excellent. A properly conducted operation should always permit the extraction of the projectile which is to be removed. Failures are rare if the posterior route and the methods of narrow access are avoided; they result almost entirely from the lack or insufficiency of radiographic aid. The operative sequelæ are simple in the great majority of the cases.

In major transpleural interventions, necessitated by mediastinal or juxtamediastinal operations, I have had healing by first intention in 70 per cent.; discharge of serous fluid at the first or first few changes of dressings, in nearly 30 per cent.; in only five or six cases did the serous fluid become distinctly purulent. This complication was apparently related to the degree of infection of the part in which the projectile was lodged. Repeatedly, however, projectiles infected by the streptococcus and other pathogenic germs were removed without untoward sequelæ. The omission of postoperative drainage of the pleura is the most reliable means for the avoidance of complications.

The statistics already referred to concern especially severe cases, many of which had been operated on unsuccessfully, and which were entrusted to me, at my request, by colleagues. No patient died in the course of the operation, nor in the first twenty-four hours, nor after six days. The total mortality amounted to 7 per cent. It is noteworthy that in five of the seven fatal cases the operation had consisted in the removal of projectiles from the root of the lung. This region would thus appear to be extremely dangerous, when it is kept in mind that the removal of eleven foreign bodies from the heart, including two in the cardiac cavities, were fatal in but one instance, and that all of the patients operated upon for projectiles in the pulmonary hilus survived. Progressive improvement of technique has led to a parallel improvement in results. In the above statistics it appears that whereas in 1916 and 1917 only 82.3 per cent. of the projectiles could be extracted, there was no failure in 1918 and 1919; likewise, whereas in 1916 and 1917 8.7 per cent. of the patients operated upon died, no death occurred in 1918 and 1919.

Conclusion.—The methods for the extraction of intrathoracic projectiles have been greatly improved in the course of the world war, but the fact must not be lost sight of that in order to guard against disappointment interventions of this class must be

positively and absolutely left to experienced surgeons working in suitable surroundings, and never to fledgling operators whose scalpels have been let loose by the war. With these reservations, all disturbing or voluminous intrathoracic projectiles should be removed.

34, Rue André.

THE IMMEDIATE CLOSURE OF WAR WOUNDS.

By RAYMOND GRÉGOIRE, M.D.

PARIS, FRANCE.

PROFESSEUR AGRÉGÉ AT THE PARIS FACULTY OF MEDICINE; SURGEON TO THE HOSPITALS.

THE idea of immediate suture of war wounds was an innovation so bold that it seemed at first, to those who could not at once grasp its significance, to be worthy of all condemnation. However, it was soon accepted by all as a rule. It constituted truly a revolution in surgical practice, but we may say today that the remarkable and unhoped for results obtained by war surgery in all its branches had their origin in the early attempts at primary closure of wounds.

One must have seen the frightful number of cases of gaseous gangrene, of infections of every kind, in the first months of the war, when it was still

FIG. 1.—Immediate suture of multiple wounds of the lower extremities; right leg, wounds of the knee and of the soft parts; left leg, wounds of the soft parts only.

thought that abstention was the best method; one must have seen the interminable suppurations, the torture of the dressings, the physical exhaustion of the severely wounded when abstention from operation was replaced by debridement—an improvement, indeed, since at least it saved life; then one could understand the importance of immediate suture and the comfort it gave us in the long trial that we went through.

The idea of the immediate suture of wounds received in battle is of French origin. From the very beginning of the war I used to suture simple wounds of the scalp and face, for we knew that they were not apt to suppurate, but the credit of having developed this practice into a method is unquestionably due to Lemaitre of Paris and Gaudier of Lille. When, in 1916, my assistant, Henri Mondor, and myself first laid before the Société de Chirurgie de Paris the results of 125 cases of immediate suture which we had practiced, approbation of our action was not unanimous, and some of the members thought that such a practice savored of audacity and imprudence. Since then it has become a general rule.

The method of immediate suture of war wounds is based upon certain principles of pathological physiology which are to-day clearly established. It is not to be applied indiscriminately, but, on the contrary, is governed by very precise therapeutic indications. It has a perfectly definite technique which assures good results. Finally, in order that

FIG. 2.—Immediate suture in a case of bimalleolar fracture by a shell fragment.

it may be applied on a large scale, and may be successful, it is necessary that the transport of the wounded be well organized. These are the points that we shall consider in what follows.

Principles of the Method.—One may accept as an established fact that every war wound is a dirty wound, consequently inoculated with microorgan-

FIG. 3.—Delayed primary suture in a case of fracture of the right humerus by a shell fragment.

isms of all sorts. The soldier's skin is, of necessity, of very doubtful cleanliness; his clothes are covered with dust, with mud, and often even with fecal matter. Although we may admit that bullets and other projectiles flying with great velocity are

aseptic, it is now clearly recognized that fragments of shells, bombs, and grenades are eminently septic. The wound then must of necessity be inoculated.

But an inoculated wound is not yet an infected one. Infection implies that the organisms have begun to increase and are germinating in the wound. Now, the studies of Policard and Phélip have established a chronology, as it were, of inoculation and infection. In the first few days following the receipt of the injury there is a sort of stupor of the region involved. The wounded tissues do not react, there is no sign of diapedesis in sections examined under the microscope; the microorganisms are not yet proliferating. In a general way, we may say this period of stupor lasts for seven or eight hours after the infection of the wound. At the end of this time the white blood cells start to invade the wounded region and the system of defense begins to organize itself; but at the same time the microorganisms begin to develop, the anaerobes being the first to proliferate. From the fortieth hour on, both anaerobes and aerobes abound in the wound.

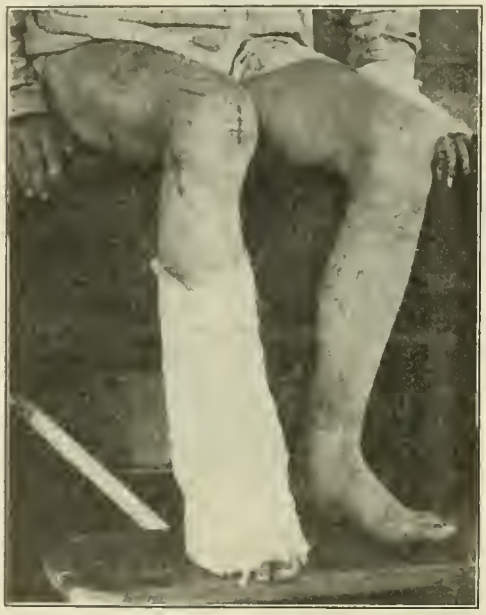

Fig. 4.—Primary suture in a case of double wound of the right knee by a shell fragment.

There exists, therefore, between the moment when the wound is inoculated and that in which it is infected a period of stasis or stupor, lasting from eight to twelve hours, that the surgeon can utilize to remove both the disorganized tissues and the infecting agents, which latter, if undisturbed, will find in these defenseless tissues a wonderful culture medium.

Do we mean to say that once the bruised tissues have been excised the wound is strictly aseptic? Certainly not. It still contains germs which the surgeon himself may have deposited there, however careful he may have been. But the normal living tissues are not as inert as a Petri dish; they are capable of defending themselves. This is what Legrand has termed the autosterilization of wounds; it touches the double problem of phagocytosis and immunity. What can be affirmed from the practical standpoint is that when vitality of the tissues is unimpaired and the microorganisms are of moderate virulence the wound will sterilize itself, and that everything that renders the forms of defense more active will increase and accelerate the process of sterilization.

Indications and Contraindications of Immediate Suture.—One may say that the great majority of war wounds can and should be sutured while they are still recent. This "precocity" of intervention is certainly the essential indication, and we must act as soon as possible. As far back as 1916 we said: "The time elapsing since the receipt of the wound is of prime importance. During the first few hours we must suture; after the twelfth hour we may make the attempt to do so; after forty-eight hours, even though the patient is apyretic and the surface of the wound is red, it would be dangerous to try it." These rules have scarcely changed since then. The studies of Policard and Phelip above mentioned give the explanation of this.

Suppuration is a formal contraindication to suture. When the wound is already bathed in pus it is too late to close it, even after resection of the infected tissues. We must then have recourse to chemical sterilization and lavage of the wound after the Carrel method.

Multiple wounds sometimes prevent us from attempting immediate suture, for in such cases the operation necessarily consumes much time and an intervention of long duration might react very unfavorably on one of these unfortunate creatures riddled with shell fragments of all shapes and sizes.

For the same reason, *shock* forbids us to interfere except in the most urgent cases, and usually obliges to defer to a later period any attempt to close the wound.

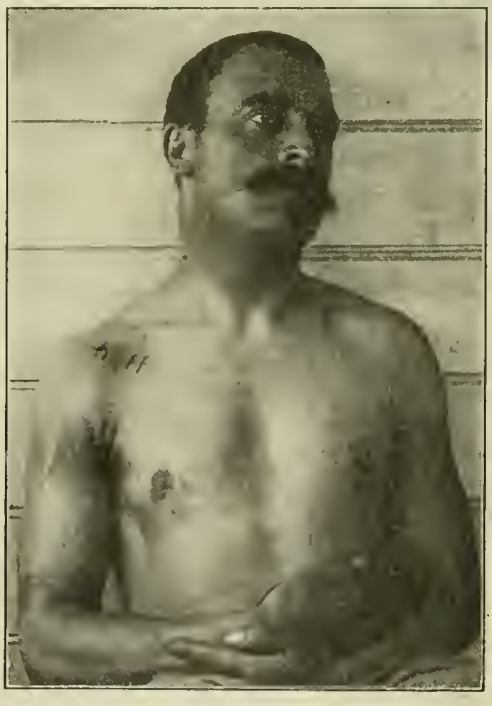

Fig. 5.—Immediate suture of a wound of the right shoulder by a bomb fragment.

Finally, *military necessity* may offer a contraindication to the immediate closure of a wound. It is necessary, indeed that the surgeon should be able to watch the patient for at least a week after the wound

has been closed. There would be very great risk in abandoning the patient or in having him transported for some distance without supervision after suture of his wound. We must, therefore, be certain that the military command has provided for sufficient hospital accommodation.

It has been said also that the method of immediate closure of the wound can be employed only during a period of calm, and cannot be utilized while fighting is going on. This is not so at all. We shall see later how the French command had organized the transport of the wounded so as to permit the suture at any time of wounds of every kind.

Technique of Immediate Suture.—The method of immediate suture rests upon the fact that the contused tissues are defenseless against microorganisms, for which, indeed, they furnish a marvellously good culture medium. We must then remove the contused and inoculated tissues. Immediate suture is only the complement of this first indispensable stage upon which the successful result depends. The wounding agent, and débris of all sorts (clothing, pieces of the accoutrements, dirt, pebbles, wood, etc., etc.) are usually lodged in the wound, and it is absolutely necessary to remove all such matter at once because of their septicity.

Fig. 6.—Immediate closure of a shrapnel wound of the left hip-joint; the missile was removed from the neck of the femur.

First Stage: "Radiological Exploration." It would be a grave mistake to attempt primary suture without first having satisfied oneself by an *x*-ray examination that no piece of projectile is present in the wound. Metallic fragments are the most frequent and the most deeply seated, but sometimes there are also other foreign bodies which can be detected by radiography, and which might, if they escaped discovery on direct examination of the wound, give rise to very grave accidents.

Second Stage: "Ablation of the Contused Tissues and of Projectiles." In the early days of this method surgeons were often content with mechanical cleaning by compresses, stiff brushes, and the curette, but it was soon apparent that this technique was insufficient. Later, surgeons went to the other extreme, and with the idea of removing the bruised tissues as one would a neoplasm—that is to say, by very wide excision—they caused considerable and unnecessary destruction. The true course lies between these two extremes. All depends upon the degree of contusion of the tissues. If the tract is clean cut, not very ragged, and if the muscles are not extensively destroyed, it will suffice to excise a zone one centimeter in thickness. This technique is easy in tangential wounds or superficial penetrating wounds; it becomes much more difficult in deeply penetrating wounds, for then wide excision is necessary.

In the case of a large wound which is known to contain a projectile, one must go on patiently to the very bottom of the tract, which must be excised, together with the bed in which the projectile is lodged. When the muscles are extensively lacerated we may have to make a very wide excision. Experience is the only teacher here, but one soon learns to recognize the hamlike tint of dead muscle, which no longer contracts upon direct stimulation with the point of the knife. Here extirpation must be carried to the line of separation between the dead and living tissues, and consequently must sometimes extend a considerable distance.

Third Stage: "Hemostasis." It is necessary to prevent any possibility of hemorrhage, however slight, for a blood clot would offer a culture medium which would be immediately utilized by the microbes remaining in the wound. The surgeon can never hope to remove all the microorganisms, but can effect only a relative asepsis, which, however, will be sufficient, provided the tissues are living and not contused, when they will be fully able to defend themselves.

Fourth Stage: "Suture." In many cases it will suffice to unite the skin and subjacent aponeurosis in one layer of suture. This has the advantage of not leaving any new foreign bodies in the wound, even though they may be absolutely sterile. In other cases, where the wound is quite extensive, one may be forced to suture in several superposed layers in order to avoid leaving dead spaces where blood and the natural secretions might accumulate. For the same reason some surgeons leave a gauze or horse-hair drain in the wound for the first twenty-four hours. This procedure seems to us, however, more harmful than helpful if hemostasis has been well done.

The subsequent course of a primarily sutured wound, provided no complication occurs, shall be as simple and uneventful as that of any operation wound, as the cicatrization of a hernia incision, for example.

We said above that the next important stage in this technique is the excision of the contused tissues and the removal of the wounding agent. This is all the more true in the sense that one can without great harm put off for a while the closure of the wound, suturing at a somewhat later and more convenient period, whereas one could not, without running grave risks, delay for several hours the removal of the contused tissue and the buried projectile.

This fact of being able to delay suture after the excision has been practised is of considerable interest from a military point of view, for when the wounded are being brought in in large numbers one must act quickly in order to be able to operate on all. After the wound has been closed the patient must be kept under observation for eight days at least, and one can readily imagine that this comports badly with the necessity of rapid evacuations. The French surgeons, Derache, Duval, Barnsby, Alglave, and many others, have shown that one may without harm and even with advantage per-

form the operation in two stages: in the first the excision is made, and then the patient, whose wound is left wide open, may be evacuated further back to the base hospital, where—24.48, or even 72 hours after the first operation—the second stage, that of suture, is practised. This is what is termed *delayed primary suture.* This mode of procedure has made possible suture of the great majority of war wounds on a mobile front and even during an attack.

Further Progress of Sutured War Wounds.—A war wound closed by immediate or delayed primary suture evolves in one of two ways: either it simply heals without incident, like an asceptic surgical wound or it shows signs of infection. In the first case the wounded man suffers no pain, his general condition is very different from that of the carrier of an open wound, the facies is excellent, the tongue is clean, and the pulse is regular; the temperature always rises at first to 38° or sometimes 38.5 C. 100.5° or 101.3° F.), but falls spontaneously on the second or third day. In a week cicatrization is completed, the sutures are removed, and the patient is discharged as convalescent.

In the second case the wound is painful, its sutured edges are swollen, and the temperature is elevated. On separating the lips of the wound a little suspicious serous fluid escapes. What are we to do in a case of this kind? Should we wait a little, or should we at once open up the wound? The studies of Tissier have established in a wholly scientific manner the course to be followed; all will depend upon the nature of the microbian agents which are in process of development, for their quality alone is of importance, their quantity having scarcely any significance. Every war wound has a special microbian character upon which its evolution depends. The anaerobic microbes become harmful only in symbiosis with aerobis; if, therefore, they are found alone in the wound it is not to be opened.

The virulence of the aerobis varies greatly. The staphylococcus is not very dangerous. If it is found alone, it will suffice to remove a few stitches in order to give vent to the pus, and it is only in exceptional cases that it will be necessary to reopen the wound completely; these sutured wounds heal a little more slowly and with incomplete union. The streptococcus, on the other hand, is very harmful, and as soon as one is certain of the presence of streptococci the wound should be opened at once. Thanks to these principles established by Tissier the method of immediate or delayed suture of war wounds rests upon an absolutely scientific foundation.

Results.—The remarkable results of immediate closure of wounds of the soft parts have led surgeons to extend the method to wounds of the bones and joints, of the skull and brain, and of the great serous cavities and the thoracic and abdominal viscera. The general principles of the technique in these cases remain the same, only certain details being peculiar to the special localization of the wound, details which it is unnecessary to enter upon here. We may, however, give some concrete results to enable the reader to judge of the value of the procedure.

Wounds of the Soft Parts: The results published by a number of our surgeons at the front (Marquis, Gros, Derache, Lemaitre, Raymond Grégoire, Pierre Duval, Guillaume Louis, *et al.*), are practically identical. Of 100 cases of wounds of the soft parts 90 can be sutured immediately or a few hours after the excision has been made. In allowing 4 per cent. of failures, we get 86 out of 100 wounded who are cured and in convalescence within six weeks.

Wounds of the Bones: Success in these cases demands a more vigorous technique and greater skill on the part of the surgeon, and consequently the cases of bone injury were transferred to special centers directed by surgeons of the highest standing. The mean of published results gives 77 per cent. of successes whatever were the injured bones. Of 133 wounds of the bones (Marquis) 26 were sutured primarily and 77 secondarily, a total of 103 closures out of 133 cases. Picot has shown that, in cases of primary wound closure, fractures of the forearm consolidated in 23 days; those of the humerus in 35 days; those of the leg in 68 days, and those of the thigh in 86 days, that is to say, in the same time as that required for the healing of simple fractures.

Wounds of the Joints: We may say that among all these injuries, the results obtained by immediate closure of articular wounds were those which at first most struck the imagination. There again the percentage of recoveries was practically the same for all surgeons. If we take the results which have been published of wounds of the knee we find an average of 90 per cent. of successful cases of immediate closure, and among these a very large number of the patients recovered very nearly if not entirely the normal function of the joint.

Military Organization.—In order that the method of immediate closure of war wounds may attain its highest measure of success, the aid of the military command is necessary. It is first of all necessary that the wounded be found and transported to the front line stations as rapidly as possible. To enable this to be done the command must have provided ways of access, relays, and automobile ambulances in sufficient numbers. Then the operating centers must be manned with a sufficient number of surgeons and with hospital accommodations proportioned to the estimated number of wounded; and as this number may be exceeded, the operating center should be connected by lines of rapid transportation with other sanitary formations further to the rear to which in cases of emergency the wounded may be evacuated who have been operated upon but whose wounds have not yet been closed, being thus ready for "delayed primary suture."

All this organization had been studied in every detail and foreseen in the French armies, and one may say that the excellent results obtained were due largely to this intimate solidarity of surgeons, directors of the sanitary service, and the high command, to which, at the annual meeting of the Société de Chirurgie of Paris, M. Mourier, Undersecretary of State, came especially to render homage.

20 Rue de l'Université.

Sir William Osler, whose 70th birthday occurred on July 12, was the recipient at that time of a book of essays written by many English and American friends. The work was in two volumes of 700 pages each.

MEDICAL RECORD.

New York, August 2, 1919.

PAROTITIS AS A POSTOPERATIVE COMPLICATION.

THIS is a somewhat rare complication, but a fairly large number of cases have now been reported and the complication assumes especial importance from the fact that it has a remarkably high mortality. When postoperative parotitis has occurred, it has usually followed an abdominal operation, very rarely operations on other parts of the body. Among the causative factors are conditions which bring about relative dryness of the oral cavity, such as high temperatures in septic states and cessation of mouth feeding, since with the diminished salivary secretion the activity of the bacteria present in the oral cavity is greatly increased and their invasion of the gland through Stensen's duct is made relatively easy.

Although, as just stated, postoperative parotitis is somewhat rare, C. U. Collins (*Surgery, Gynecology and Obstetrics*, April, 1919) reports the occurrence of four cases in the course of a single year. That was in 1915 and he has had but three before or since that time. In a total of 6,100 operations but seven cases developed parotitis, and of these patients four died. All of these patients had been in the same hospital and all had had abdominal lesions of one kind or another.

In reviewing the literature Collins found interesting articles by Rolleston and Oliver on secondary parotitis, based on the study of 1,000 cases of medically treated gastric ulcer. They found that in 470 patients treated by oral starvation there were 21 cases of parotitis, or 4.5 per cent., while in 530 patients who were allowed something by mouth there were but two cases, or 0.4 per cent. Their conclusions were: (1) Secondary parotitis may complicate cases of gastric ulcer treated medically by oral starvation; (2) it occurs two and a half times more frequently in such cases of gastric ulcer than in cases allowed fluid by mouth; (3) it is an outcome of the dry condition of the mouth and mouth washes do not prevent its recurrence; (4) it is more often unilateral than bilateral; (5) suppuration occurs in about one-fourth of the cases and this constitutes a grave complication.

Collins also refers to another very suggestive article recently published by W. S. Fenwick, entitled "The Prevention of Parotitis during Rectal Feeding." Fenwick believed that the infection ascends Stensen's ducts, and he tried various measures to keep the mouth clean, but they were not successful; he then tried to promote a continuous flow of saliva by having the patient chew or suck various articles; and he finally found that the sucking of a rubber teat produced the desired effect. The efficacy of this procedure was demonstrated by the fact that after he had adopted the method he treated over three hundred cases by rectal alimentation without a single case of parotitis.

In the study of his cases Collins came to the conclusion that the patients had not received sufficient fluids, that there was inactivity of the parotid glands with dryness of the mouth, and that the inactivity of the glands predisposed to infection. A study of the practical results of trying to give fluids per rectum convinced him that the patient did not get near as much fluid by that method of administration as he had tried to make himself believe. He found that about half of the patients retained very little, if any, of the fluid, and the remaining patients retained perhaps half of the fluid administered. After two or three days' administration the rectum usually became irritable and retained none of the fluid. He therefore decided that the first problem was to keep the parotid gland actively secreting and passing a current of secretion down Stensen's duct into the mouth; and the second was to keep the patient's body supplied with sufficient fluid.

From the study of his own cases and his review of the literature, Collins reached the following conclusions: (1) Postoperative parotitis is more apt to occur after abdominal operations than after those on any other part of the body. (2) Its development is favored by a dry condition of the mouth and a lack of fluids in the body. (3) The infection usually ascends through Stensen's duct. (4) In patients whose abdominal condition makes it necessary to withhold food and drink from the mouth and stomach for a time, prophylactic treatment should be instituted. (5) The mouth should be kept clean and moist by its own secretions and the body should be abundantly supplied with water. (6) A good way to excite the secretions of the mouth and to keep a current of saliva running down Stensen's duct is to allow the patient to suck on a stick of lemon candy after operation. (7) A very accurate and effective way to supply the body with fluid is to administer salt solution by hypodermoclysis. If this is done according to Kânavel's directions, there will be no pain in the administration and very little discomfort. (8) If the prophylactic treatment fails and parotitis develops and the inflammation is increasing, or is no better by the third or fourth day, the gland should be uncovered by a free incision and punctured in several places with blunt forceps and the incision packed with wet sterile gauze, as suggested by Blair.

GONORRHEAL VACCINES.

Vaccines have been for some time past employed as a prophylactic measure, but at present they are being experimentally used as a therapeutic means. Of late a certain number of papers have appeared in the United States and England on the use of vaccines in gonorrhea, but for some unknown reason the writers overlook the work of Nicolle and Blaizot carried out at the Pasteur Institute in Tunis, and it is to their researches that we would refer here. These researches passed through three phases. In the first, the experimentors used a living vaccine which they injected into either the veins or muscles, according to whether the subject was an adult or a child. In the latter the results obtained were very rapid but a sharp general reaction invariably occurred.

In the second phase of their researches, Nicolle and Blaizot employed a sensibilized living vaccine prepared according to Besredka's method. The results obtained were exactly the same as those when ordinary living vaccines were employed, namely, a manifest therapeutic action in extraurethral complications, particularly in ophthalmia, but with a reaction quite as violent as when serum had not been added. These living vaccines are difficult to handle on account of the fragile nature of the bacterium, therefore Nicolle and Blaizot resorted to fluoride solutions which resulted in their obtaining a more stable vaccine, but which was too toxic to be easily manipulated. Besides, the gonorrheal complications were in no way influenced by this treatment.

A notable progress was realized by the addition to the gonococcus of a bacterium which is frequently associated with Neisser's organism during a gonorrhea and its complications, which these *savants* have termed synococcus. Although this organism does not possess such manifest specific properties as the gonococcus, its therapeutic power is very evident in the urethral complications of gonorrhea, particularly in the so-called rheumatism. The combination of the synococcus and Neisser's organism in the same vaccine allowed Nicolle and his coworker to obtain not only an active product in relation to the two microbes, but still more, to heighten the proportion of microbic bodies in the vaccine, that is to say, to increase its therapeutic power without increasing its toxic properties.

As to the technique of inoculation one-half cubic centimeter of the vaccine is given subcutaneously or intramuscularly. It should be diluted in physiological salt solution, the subcutaneous cellular tissue of the flank or the muscular mass of the gluteal region being selected for the injections. If the vaccine is given intravenously one-eighth of a cubic centimeter is passed into one of the veins of the elbow. If it is necessary to act quickly an injection is given daily and later on every other day. In the acute urethritides or acute gynecological infections, inoculations of the vaccine are to be made every two days and later every third or fourth day. In the chronic forms of gonorrhea the inoculations are given every third or fourth day, always bearing in mind that most cases are obstinate to all forms of treatment.

Nicolle believes that the vaccine acts more rapidly and completely on the complications of the urethritis than on the urethral process itself. Its antiphlogistic action is immediate, particularly in arthritis and epididymitis. It likewise shortens certain complications such as subacute ureteritis and is especially efficacious in rheumatism. Its effect on the urethral discharge is less absolute, although this lessens after a few days and the pain subsides. The local complications are greatly ameliorated in the male, while in the female a certain number of cases of metritis, oophoritis salpingitis, and also vulvovaginitis are favorably influenced. Such results are unquestionably interesting but the fact must not be overlooked that Nicolle's vaccine is not a cure-all, and that much still remains to be sought for in the treatment of gonorrhea, and, above all, its complications.

AN EARLY OUTBREAK OF INFLUENZA IN THE ITALIAN ARMY.

It has now been pretty well established that soldiers stationed at Alessandria were attacked with influenza at about the close of the first half of the month of May, 1918, or some days before the great Madrid outbreak. Apparently a mild wave of disease swept over the locality and soon vanished so that not much attention was paid to it, especially as no fatalities occurred. Perhaps two weeks later the malady appeared in other localities in the same area especially where men were crowded together, and exhibited cases with pulmonary complications. Bacteriological studies were negative. This wave in turn having run its course, only sporadic cases were in evidence in the last half of July. But in the first days of August a wave of greater malignancy appeared and now for the first time fatalities began to accumulate. This outbreak seemed to have much greater diffusibility than either of the preceding and a climax in both incidence and death rate was present in September and the first part of October. The epidemic now bore the complete stamp of the severe influenza universally present throughout the world.

The two small and early waves of May and June which occurred before and contemporary with the outbreak at Madrid attracted little attention and doubtless as elsewhere in Italy suggested only pappataci fever. Highly significant is the fact that the disease first appeared toward the second half of May and only in soldiers. Whence came the infection of these soldiers? The latter naturally were able to spread the disease among the civilians. There had been vague remarks about cases in Spain for a month before the Madrid outbreak, and the history of influenza in Puerto Rico seems to show that the disease was borne there from some Spanish city other than Madrid, perhaps be-

fore the latter sustained its outbreak, or possibly from the Continental United States, where some authorities still believe that the present pandemic originated or acquired its epidemic character. The problem of the genesis of grippe and the part played therein by soldiers may recall the controversies about the origin of the pandemic of syphilis in the fifteenth century.

Delayed Reaction to Alcohol Expressed as Fear States.

An episode which occurred many years ago and which was not properly documented at the time cannot of course be reported today as a case but its recital may give rise to speculation. The subject was a man in his late twenties who decided to test upon himself under observation the action of alcohol in the form of whiskey. He drank half a pint of the latter during an entire evening, slept as usual, awoke in his usual subjective state, and ate well at breakfast. He had not at any period since drinking experienced anything unusual. He went on a steamboat excursion to a favorite resort and upon arrival sought the wildest and most deserted locality which looked out on the open ocean. The hour was about half past ten, or 12 hours after his final indulgence. Suddenly without the least prodrome he experienced an acute fear of death or loss of mind or identity with no corresponding physical manifestations. He feared that despite himself he would scream aloud. During the seven hours which expired before he reached town he suffered continually from his agony with only the mildest of intermissions. He associated his sufferings with the whiskey and the thought of the latter caused a feeling of intense repugnance. The man who at his request had watched him during the experiment only laughed at his tale of woe and told him that a cocktail would promptly "normalize" him. Upon the receipt of this intelligence his symptoms promptly improved and the prescription completed the cure. A material explanation of this behavior does not seem adequate when some of the basic facts are considered. The subject came of a neurotic stock with a few cases of alcohol addiction and had always had instilled into him a fear of whiskey which may have entered into the formation of some complex. As an adolescent he showed many psychasthenoid symptoms, such as obsessive or compulsive acts, and had always exhibited a markedly shut-in and introspective personality; his ideals were peculiar, and all in all he was not well adjusted to his environment. The mere ingestion of the drug might have added to the original fear of the same. The nature of the inhibitions which delayed the reaction and the factor which suddenly removed them can only be surmised, but the sense of loneliness and isolation which is a primitive and universal source of fear seems to have precipitated the crisis. Both the symptoms and treatment showed a strong suggestive element.

Anergia and the Predisposition to Infections.

Some simple term is necessary to render the expression "diminished resistance to infection," and von Pirquet once used the term anergia for the purpose, but only in the sense of a temporary forfeiture of natural immunity, or transient inability of the organism to manufacture antibodies. (Galeotti in *La Riforma Medica*, May 31.) Thus the cutireaction in tuberculosis may fail because for one or another reason no antibodies form to sensibilize the reaction. In scarlatina about one-third fail to respond to a cutireaction, while in measles the degree of anergia is much higher. To give the term an added significance we may state that the anergia which is so common in influenza is responsible for the attack by secondary microorganisms. The cause of such anergia is evidently the filtrable virus of authors. To substitute the word anergia in this case does not of course add anything to our knowledge, but when the word signifies the inability to generate sensibilizing antibodies, as seen in the phenomenon of absent cutireaction, we have something tangible to go upon because these antibodies include bacteriotropic and bacteriolytic substances and are related to the opsonins. Alien germs which may reach the blood become innocuous in favorable cases but when no antibodies can form, the bacteria destroy the bactericidal substances and overwhelm the tissue cells. In certain cases the opposing forces are evenly balanced.

News of the Week.

Army Medical Corps Needs Officers.—The War Department announces that 600 men are to be commissioned in the Medical Corps of the Army. These men are to be chosen from the present personnel and their places in the military establishment will be permanent. The Adjutant General is to make the appointment in the following order: Emergency medical officers now in the service; members of medical section, Officers' Reserve Corps, who served with credit as officers during the war, and former emergency medical officers who served with credit during the war. Applicants considered satisfactory by the Adjutant General will be authorized to appear before examining boards to determine their mental, moral, and physical fitness and professional qualifications. Applicants serving with the A. E. F. will file applications with the Commanding General, who will select candidates for examination. The present law provides that persons hereafter commissioned in the Medical Corps shall be citizens of the United States, between the ages of twenty-two and thirty-two years, and original appointments shall be in the grade of first lieutenant. All persons eligible for and desiring appointment should address a letter of application for examination to the Adjutant General of the Army without delay. The following data must be furnished by applicants, and any less data than enumerated will not be considered satisfactory and will lead to delay: (*a*) Name in full (initials not acceptable). (*b*) Date of birth. (*c*) Place of birth. (*d*) Permanent home address. (*e*) Medical school from which graduated with dates. (*f*) Professional experience. (*g*) If an officer who has served during the emergency—complete statement of military service, setting forth (1) the organizations in which served and inclusive dates, (2) present organization if still in the service, (3) grade in which originally appointed, (4) present grade if

still in the service, (5) date, place of discharge, and rank at time of discharge if no longer in the service. (*h*) Statement of any service as a contract surgeon, in the Medical Reserve Corps or in the Medical Section, Officers' Reserve Corps. (*i*) In cases of alien birth—(1) documentary evidence of naturalization, (2) if naturalized through parent, documentary evidence of father's naturalization and sworn statements from two reputable United States citizens establishing relationship between candidate and his father. It is the present intention to hold this examination on August 25, 1919, and consideration cannot be given any application which is not received in time to enable action to be taken on it by the Surgeon General prior to August 16th.

A Medicinal Plants Garden.—The University of Michigan has decided to establish an experimental garden of medicinal plants after plans submitted by Dr. Henry Kraemer, Dean of the College of Pharmacy. The financial support of the undertaking is promised by Frederick Stearns & Company. As soon as experiments demonstrate that certain medicinal plants can be grown profitably, drug farms will be established. Druggists located in the smaller towns and cities where farm and garden land is only a short distance away will have the opportunity to take up a new and perhaps lucrative industry—the growing of medicinal plants.

Home for Aged and Infirm Physicians.—An application for the incorporation of "The Physicians' Home" has been approved by Supreme Court Justice Ford. The purpose of the corporation is to build and maintain a home for aged and infirm physicians and their wives or widows, and to assist them in any other way feasible. The incorporators include Drs. Graeme M. Hammond, Robert T. Morris, Max Einhorn, Ralph Waldo, Alexander Trautman, Albert G. Weed, Wolff Freudenthal, Silas F. Hallock, and Daniel Cook, and Supreme Court Justice Bartow S. Weeks.

State Care for Tuberculous Men.—The Tuberculosis Committee of the New York State Charities Aid Association announces that the names, but not the addresses, of 3,411 men who were rejected by the local draft boards in this State, have become available. Steps are being taken by the association, in conjunction with the State Department of Health, for placing these men under the care and assistance of local health authorities and tuberculosis societies.

Foundation for Destitute and Abandoned Children.—The will of Mrs. Rosa E. Spang of Pittsburgh, who died on June 22, establishes a fund of about $1,000,000, to be known as the Rosa Spang Foundation, which shall be devoted to the education and instruction of selected children taken from orphanages and institutions. The executors and directors of the foundation are former Attorney General George W. Wickersham, Colonel Michael Friedsam, and Dr. Henry Dwight Chapin.

Capt. Philip Moen Stimson, formerly of New York, who went to the front in 1917 and was severely wounded in the shoulder, and who for nearly a year has been Adjutant in the American Red Cross Military Hospital No. 2 in Paris, has received from General Pershing a citation for exceptionally meritorious and conspicuous service.

Correction.—In our report of the proceedings of the Section on Surgery of the American Medical Association on page 172 in the issue of July 26, it was stated that a paper on "Gas Bacillus Infection" was read by Dr. Frederick T. Von Reuben, Jr.; this should of course, have read, Dr. Frederick T. Van Beuren, Jr.

New York Towns Employ Public Health Nurses.—The Essex County Chapter of the American Red Cross has voted to employ a public health nurse. Wheatland and Mount Morris have appointed community nurses and appropriations for this purpose have been made by Fort Plain and St. Johnsville. Madison County has recently employed a county tuberculosis nurse.

Relief Unit Off for Serbia.—A party of twenty doctors and nurses, sent by the Serbian Relief Committee of America, sailed on July 26 on the President Wilson for Patras and thence to Salonica, where they will join Major William H. Cressy, Director of Medical Relief for the Committee in Southern Serbia. The party is under the direction of Dr. B. W. Brush, U. S. N., and includes Drs. Evangeline Caven, John Hraba, A. Elizabeth Ingraham, Elizabeth Kleinman, Lilla Ridout and Gertrude M. Streeper.

Tuberculosis in New York Herds.—Dr. W. J. Hoskins, Dean of the Veterinary School of New York University, in speaking before the twenty-ninth annual convention of the New York State Veterinary Medical Society, in Brooklyn, on July 24, stated that in a large measure the high cost of meat, milk, and butter is attributable to the large numbers of cattle destroyed because of tuberculosis each year and the fact that farmers have been unable to replace cattle that have been thus sacrificed. He values the cattle that succumbed to tuberculous disease last year at $8,000,000, and urges that the Legislature be petitioned to appropriate $2,000,000 annually to fight this disease among livestock. He claims that ten thousand persons die annually in this State from tuberculous diseases contracted from dairy products, and that 40 per cent. of mothers and twenty-three per cent. of the infants are under-nourished because of the poor quality of the milk produced by unhealthy cows. The society adopted resolutions urging that dairy farms and milk bottling establishments be systematically inspected at regular intervals.

To Begin New Sing Sing Prison.—It is announced that the State is ready to authorize an immediate beginning on the new buildings for Sing Sing prison which has long been needed because of the antiquated and unsanitary condition of the old buildings. The excavating has been practically completed and the work of putting in the foundations is to be begun immediately.

Request for Cooperation of Volunteer Health Organizations.—The New York State Department of Health, in order to secure the maximum of cooperation between existing health agencies, is desirous of securing an up-to-date list of all organizations working for public health in any of its various divisions. Reports and regular publications of these organizations are solicited and in return the State Department of Health will be

glad to send such of its publications as are requested. It is particularly desirable that the Health Department shall be kept informed of new exhibit material, posters, panels, lantern slides, films, etc., in order that the exhibit work may be coordinated.

Smallpox in Wake of Small Circus.—According to a communication from Pennsylvania to the New York State Department of Health, cases of smallpox have appeared in the wake of a small circus which has been traveling through Virginia, Maryland, and Pennsylvania, and was last heard of in Ohio. Health officers of New York State are requested to be on the lookout for this circus and to be prepared to apply the necessary measures.

Doctors Licensed in North Carolina.—Eighty-two physicians, including twenty-three reciprocity applicants, have been licensed to practise medicine in North Carolina after successfully passing the examinations of the State Board of Medical Examiners in Raleigh on June 24-27.

Professor Albert Doderlein, the distinguished gynecologist, is reported to have been among the hostages shot in Munich during the recent political disturbances. He was born in 1860 and graduated in 1884, and, after holding the chair of obstetrics and gynecology in the Universities of Groningen and Tübingen, accepted a call to Munich. He was the author of numerous publications on various gynecological subjects.

Dr. Ernest B. Emerson has resigned the position of superintendent of the Rutland State Sanitarium in order to accept a position in a private hospital in Brockton, Mass. The vacancy in the Rutland State Sanitarium will be filled by Dr. Leon A. Alley who has been the assistant superintendent.

Dr. Charles E. Wells has accepted the position of superintendent of the Newport (R. I.) Hospital to fill the vacancy caused by the resignation of Dr. Norman McLeod.

Dr. Charles Theodore Graham-Rogers of New York, who served in the war as a line officer with the 27th Division, has been appointed Captain in the Medical Corps attached to the 47th Infantry, New York Guard.

War Work of Post-Graduate Hospital Commended.—The work of the medical staff attached to Base Hospital No. 8, at Savenay, France, the unit sent by the Post-Graduate Hospital of New York, is highly commended by Surgeon General Ireland in a report to the Trustees of the institution just issued. The hospital was started with only 127 beds in August, 1917, near the Port of St. Nazaire, and at the time of the signing of the armistice had a bed capacity of 18,000 beds. Surgeon General Ireland has requested that the personnel of the unit be kept together for future emergencies and a similar request has been made by Col. C. H. Connor, Assistant Director-General of Military Relief. The organization of the unit was effected by Dr. Samuel Lloyd, who was director of the Surgical Division. Lieut. Col. Joseph F. Siler was Commanding Officer, and Major Julian Estill was Director of Medicine.

Jacobi Memorial Hospital Planned.—A campaign committee of which Dr. S. Robert Shultz is the executive director has been organized to raise funds for the erection of an Abraham Jacobi Memorial Hospital. A survey of the hospital facilities of New York City shows that the Washington Heights section is particularly lacking in hospital accommodations and it has been decided to erect the hospital in that locality. A resolution will be introduced in the Board of Aldermen at the first fall meeting proclaiming Heights Hospital Week from November 15 to 22. Registration of volunteer workers for the fund has been begun at the headquarters of the committee, 975 St. Nicholas Avenue.

Paris Physicians Double Fees.—A cablegram from Paris states that beginning July 8 Paris physicians will charge double their pre-war rates. Fees for night work will be three times the pre-war rate.

Willimantic Doctors Raise Fees.—The Willimantic Medical Society, at a meeting held June 28, voted to adopt a new fee schedule which went into effect on July 1. According to the new schedule house visits will be $2 and office visits $1.50. Calls between the hours of 9 P. M. and 7 A. M. are $3. A traveling fee of fifty cents a mile is charged. A charge is made for advice given over the telephone.

Suicides Show Increase.—According to statistics published by the Save-a-Life League, the object of which is to prevent suicide, show that from January 1 to July 1 of this year more than 2000 persons have killed themselves in this country. The oldest of these was 100 years of age and the youngest 10 years. During the past six months 175 children in this country have taken their own lives. Of these 104 were boys and 71 girls. The favorite method of the boys was shooting, while most of the girls chose poison. The report points out that the laws against the sale of poisons and the possession of firearms should be more strictly enforced. In 1915, before the organization of the "Save-a-Life League" there were 956 suicides in New York City. In 1916, after the organization of the League, there were 337. Last year there were 752. During the last six months the number was 385. It is thought the increase during the past two years is due to depression because of the war and because of war losses. An increase in the number of women who take their lives has been noted. The ratio used to be 1 to 4, while it is now 1 to 3. It is believed this is due to the active place women are assuming in business and politics.

Memorial Hospital for Staten Island.—A hospital is to be established in the Tillinghast House, Prince Bay Road, Staten Island, N. Y., which is to be incorporated as the Richmond County Memorial Hospital. It is to be a memorial to the young men of Richmond who gave their lives in the war and is to be established by a fund amounting to $30,000 raised by the manufacturers and residents of Staten Island between Great Kills and Tottenville.

Charitable Bequests.—By the will of the late Oliver B. Wood of Camden, N. J., the sum of $30,000 is bequeathed to Cooper Hospital, for the endowment of five free beds; and the sum of $5,000 to the West Jersey Homeopathic Hospital.

The will of Warren Snyder bequeaths $10,000 each to the Hudson Hospital, Columbia County, N. Y., Hospital and the Brooklyn Home for Consumptives, and to the Long Island College Hospital, for hospital purposes, $5,000.

By the will of Marion H. Creswell of Philadelphia the sum of $5,000 is bequeathed to the Philadelphia Home for Incurables, for the endowment of a free bed in the children's ward; and the sum of $2,000 to the Children's Seashore House at Atlantic City.

By the will of the late Araminta A. Herman of Allentown, Pa., the sum of $1,000 is bequeathed to St. Luke's Hospital at South Bethlehem, $1.000 to the Allentown Hospital.

By the will of the late Annie H. Wilson of Conshohocken, Pa., the sum of $5,000 is bequeathed to the Charity Hospital at Norristown.

By the will of the late Emma C. M. Simpson of Lower Merion, Pa., the sum of $500 is bequeathed to the Bryn Mawr Hospital.

By the will of the late Rosa Strauss of New York City the sum of $1,000 is bequeathed to the Pennsylvania Hospital and the sum of $500 to the Jewish Maternity Association of Philadelphia.

By the will of the late Sarah A. C. Lloyd of Philadelphia bequests are made as follows: $25,000 each to the Children's Country Week Association, the Children's Homeopathic Hospital, the Children's Aid Society, Women's Homeopathic Hospital.

Infant Mortality Rates in the United States.—A recent report issued by the New York Milk Committee gives a summary of infant mortality rates for the year 1918 which shows that the honor infant death rate among cities of 100,000 or more was attained by San Francisco, which with a population of above one-half a million lowered its baby deaths from 73.6 per 1000 births in 1917 to 57.2 in 1918. Seattle was not far behind with a rate of 63.4. The average infant death rate for cities of over 100,000 population is 104. The rates of the larger cities are as follows: Chicago, 104.3; Philadelphia, 126; Boston, 114.9; Baltimore, 147.8; Pittsburg, 122.5; Buffalo, 121.5; Milwaukee, 108.2; Cincinnati, 104.1; Newark, 104.7; New Orleans, 123.3; Washington, 110.9; Jersey City, 118.7; Louisville, 117.4; Birmingham, 133.5; Memphis, 145; Scranton, 144.3; Richmond, 146.3; Fall River, 161.3; Lowell, 159.1; Albany, 107.4. Three cities having below 50,000 population report infant death rates below 50 per 1000. These cities are: Brookline, Mass., with a rate of 35.4; Madison, Wis., with 38.1, and Pasadena, Cal., with 43.8. In New York the infant mortality rate for 1918 was 92; in Reading, Pa., it was a little over 200.

Americans in London to Found Hospital.—Preliminary steps have been taken toward the establishment of an American Hospital in London. The hospital is an outgrowth of the war and will be open for the medical and surgical treatment of patients of all classes, irrespective of creed or nationality. During the war there was the closest cooperation between British and American medical men and the British schools were thrown open widely to large numbers of Americans who had gone over to help care for the sick and wounded. It is desired to continue this close relationship and to provide an opportunity for research and advanced teaching for graduates of other countries. It is hoped that the proposed institution will become the headquarters of American medicine in Europe. Lord Reading, who presided at the meeting at which plans were discussed, expressed the belief that such an institution would have a marked effect on the relations between the two countries. Among the original Board of Governors of the institution are American Ambassador Davis, R. Newton Crane, Francis E. Powell, Walter Blackman, J. Blair Macafee, F. C. Vanduzer, George M. Cassatt, George A. Mower, and Wilson Cross. Philip Franklin, Fellow of the Royal College of Surgeons, is the honorary secretary. The medical committee for Great Britain consists of Sir William Osler, Sir Arbuthnot Lane, Sir Humphrey Rolleston, Sir John Bland-Sutton, J. Y. W. MacAllister, and Philip Franklin. The medical committee for the United States consists of Drs. George W. Crile, W. J. Mayo, Albert J. Ochsner, Rudolf Matas, and Franklin Martin. No detailed plans have yet been formulated, but it is expected that it will involve an expenditure of $10,000,000, and subscriptions will be sought in both the United States and Great Britain.

Serbia's Need of Health Agencies.—According to a communication from Colonel Homer Folks, who recently made an exhaustive survey of the Balkan States for the American Red Cross, the death rate from tuberculosis in Serbia during the German occupation reached the astounding figures of 1453 in every 100,000. There are no accurate figures on the ravages of typhus fever and influenza, but infant mortality has increased alarmingly. Before the war the birth rate of Serbia was higher than her death rate and her population was increasing at the rate of 85,000 a year. Now it is accordingly increasing. As a remedy for this depletion Colonel Folks states that Serbia needs money, trained workers, training schools, and educational campaigns.

Obituary Notes.—Dr. Edward W. Cowles died at his home in Plymouth, Mass., on July 25, aged 82 years. Dr. Cowles was a graduate of Dartmouth College in 1859, and of the College of Physicians and Surgeons, New York, in 1863. He was well known as an alienist. He was a trustee of Clark University, for many years professor of mental diseases at the Dartmouth Medical School, and also lectured at the Harvard Medical School.

Dr. Edwin S. Moore, a graduate of the University of Minnesota College of Medicine and Surgery, in 1894, died at his home in Winona, Minn., on July 14, aged 48 years.

Dr. David Crary, Jr., a graduate of Yale Medical School in 1869, and physician at the Hartford County jail from 1875 until July, 1910, died at his home in Hartford, Conn., on July 10, aged 77 years.

Dr. Thomas Franklin Mayo of Newtonville, Mass., a graduate of Tufts College Medical School in 1907, for many years connected with the Massachusetts General Hospital, died suddenly in a hospital in Macon, Ga., on July 13, aged 41 years.

Correspondence.

THE CAMPAIGN AGAINST NARCOTIC ADDICTION.

To the Editor of the Medical Record:

Sir:—An alarming situation regarding the case of the drug addict has been created in this city, and physicians and druggists are almost unanimously deciding that under present conditions of administrative uncertainty they will not have anything to do with opiates or with those addicted to them. A very small proportion of the sufferers from this disease have complied with the recent regulations requiring their registration, numbering, photographing, personal identification, giving of employer's name, etc., at the Board of Health, carrying with this, as it does, considerable power to the Board of Health to decide and determine on the duration of their treatment, and potential if not actual power over the clinical and therapeutic efforts of the practitioner of medicine. To those familiar with addiction-disease and its sufferers, it must be apparent that such registration would not be regarded with entire confidence by persons having social, personal, and economic interests to protect. The dangers of blackmail and exposure, and the certainty of a very humiliating experience, would tend to keep from such registration all decent persons who could possibly avoid it.

It was stated at a recent hearing in the Board of Estimate that such measures as had been enforced by the Department of Health lay entirely without its proper function and probably without its legal rights and duties. However, this may be, it is to be deplored that the Board of Health did not give sufficient attention to the scientific aspects of this disease before promulgating its very stringent regulations, and did not at an early date attempt to secure the cooperation of the medical professsion in the handling of this disease, for a campaign of public health education along non-spectacular lines is certainly, and has always been, one of the greatest needs of the addiction situation. Certainly, if these things are beyond the legal activities of the Board of Health, as was suggested at a meeting of the Board of Estimate, and as is believed by many, the powers of the Board or their absence should have been determined before an attempt was made to apply them to physicians and sick people.

Something is radically wrong when the newspapers report a great increase in underworld traffic and peddling, and when honest practitioners of medicine are afraid to attend to the legitimate needs of deserving sick people. These facts are brought vividly to my attention by the scores of physicians, druggists, and addicts who daily visit the offices of this bureau. The immediate need is for physicians to make the best of the situation until the situation can be cleared and defined, and the medical organizations can be brought to a practical activity in the guidance and protection of their honest members. Practitioners and druggists should not abandoned suffering humanity to the criminal underworld traffickers in narcotics.

Blame is placed by many for part of the panic upon the action of the Federal Department of Internal Revenue in their recent arrests and their new regulations. Nothing as to the practical interpretation and administration of these new regulations has yet been announced by the Revenue Department, which is urging all honest practitioners to care for the addicted sick. Certainly physicians should look to this department so to interpret and administer these regulations and provide proper exemptions, that the clinical and intelligent handling of worthy addiction sufferers by honest practitioners of medicine will not be made impossible.

The immediate literal compliance with these Federal Regulations will work present hardship and temporary injustice, but like the old regulation demanding routine reduction of dose irrespective of the clinical needs of the case, they will undoubtedly be liberally interpreted and intelligently enforced so as to work no hardship to the honest and worthy and give latitude to the intelligent treatment of the disease.

Whatever may be the outcome of the present situation, physicians and druggists should not abandon the suffering sick, realizing that opiate addiction is, in its withdrawal symptomatology, one of the most agonizing of all chronic physical ailments.

The most urgently required activity from our Boards of Health and medical educational organizations is the spreading of some practical and possibly applicable clinical information as to the handling of this disease.

A. R. Parkhurst,
Director Bureau of Narcotic Research.
47 West Forty-second Street.

OUR LETTER FROM PARIS

(From Our Own Correspondent.)

Paris, July 3, 1919.

Saving Belgian Babies.—If the struggle against child mortality in Belgium has been successful, as all the reports from the various children's organizations prove, this is largely due to such societies as "The Little Bees" which have established canteens for children from the moment of their birth until they reach the age when they have learned to care for themselves, and have also established maternal canteens, where mothers are given every care and instruction. These canteens are given full credit for reducing the child mortality, which in 1914 was 15 per cent. of the births, to 11 per cent. during the last two years of the war. And they are also given full credit for the arrest in the increase of the number of weak children throughout Belgium. The canteens are still feeding and giving daily medical consultations to thousands of children and mothers, and experience shows how much there is yet to be done to insure the future of the Belgian race and still further to decrease the mortality among children. More than 5,000 babies are fed daily in canteens in Brussels alone, and almost as many mothers are taught to observe the rules of the scientific care of their children, all of which gives some idea of the duties of "The Little Bees," which organization has charge of most of such work.

"The Little Bees" was organized to help children before the war, but has greatly developed from year to year. During the first week in August, 1914, the Queen and Princess Marie Jose gave the society their support and immediately a new program was drawn up, providing for some five or six new branches. Four canteens for feeding children under three years of age were opened, and were in running order as early as August 8, 1914. That number was increased from week to week in every quarter of Brussels, until there were soon as many as fifty operating, all of which are still open to administer to the wants of the children. The babies receive the full amount of pure milk and any other special food that the doctor prescribes, and medical care is given them under the direction of Doctor Maurice François. They are weighed every day and their progress is watched carefully. The maternal canteens of Brussels are also a part of the work of "The Little Bees." The future mothers and the nursing mothers are looked after as carefully here as are the children themselves.

In addition to these fifty canteens, "The Little Bees" also opened canteens for weak children from three to seventeen years of age. The first of these was opened in May, 1915, and now the number has reached seventy-eight. The women of Brussels who remained throughout the occupation by the enemy and cared for these children under the most trying circumstances are still at their posts.

The end of the war in no way caused a let-up in this work for the children. On the contrary the women realize more than ever that the future of Belgium depended upon these children and they have grown so interested in helping the central commitee in its important work that they are determined to devote their time to it for several years, or as long as it ih necessary.

While "The Little Bees" has become the chief organ of the Central Committee in protecting the youth of Belgium, there are various other individual organizations on the same lines that have helped to care for thousands of children. Among them is the committee called "Le Bon pour Les Petits de Saint-Gilles" of which Mme. Leon Vandenperre is the president. She, like the other women of Belgium who have been interested in the children, remained throughout the occupation and fitted up a canteen where mothers could bring their babies to receive proper nourishing food and daily medical attention. This organization was founded in 1904. During the war its activities were increased six times. An average of 750 children under three years of age were fed every month during the war at the headquarters, and as many more mothers and older children received help here. The amount spent for milk, alone for one year was 160,396 fr., which gives some idea of the work that has been accomplished.

American Ambulance Corps Demobilized.—The headquarters of the United States Army Ambulance Service with the French Army at 47 rue de Ponthieu will be closed and the headquarters personnel under the command of Lieut. Colonel William McFarland, Chief of Service, will leave Paris for Brest some time during the early part of July. The demobilization of the U. S. A. A. S. with the French Army will thus be completed and the word "finis" written to a history of an organization unique in the military annals of the world. The U. S. A. A. S. with the French Army had its beginning in the independent American ambulance services, the activities of which antedate by at least two years the entry of the United States into the great war. Its members were the first soldiers of the American Army to be under German fire and were for many months, so far as the French armies in the field were concerned, the only tangible evidence of American military participation. No other service can boast of more glorious deeds than those which adorn the history of the U. S. A. A. S. with the French Army. A number of its drivers during the great drives of 1918 continued to evacuate the wounded after they themselves had become casualties. One section, S. S. U., 502, was gassed almost to a man. In an army essentially democratic in its plan of organization, the U. S. A. A. S. remained a corps d'élite. It numbered among its privates men who by reason of their technical equipment might easily have been field officers in other branches. Perhaps thirty per cent. of its members were men with college degrees and forty per cent. were undergraduates.

Red Cross Nurses Decorated.—Two American Red Cross nurses, Mrs. Carolyn McNulty and Sarah Thompson, have been decorated with the Croix de Guerre by Lieut. Col. Hill, Commanding Officer of Evacuation Hospital No. 49, Coblentz, in the presence of the entire hospital personnel. The decorations were conferred for exceptional bravery shown at Baccarat when the nurses pluckily stuck to their posts during a terrible air raid.

Medical Instruction by Camera.—The training of medical students is the latest development of the "movies". Various experiments are being tried in all countries, one of the latest being a remarkable film lesson in anatomy. A skeleton was taken to pieces on the screen, the importance of the various parts demonstrated, and it was then reconstructed, the effect being much stronger than if these facts had been merely gathered from a text-book. Operations by important surgeons are being recorded by Cinema photographers, and they will then be used through the country in all the medical colleges for practical instruction. The life of a film may be short. But if it is given only ten years, this means that during that time thousands of students will be able to benefit by first hand knowledge instead of the relatively small number who can be present in an amphitheater during the actual operation. Not only students in the country where the operation was performed, but others all over the world, will be able to benefit by one man's skill. A special lens has been invented which shows the details more clearly than in an ordinary film. In France, the same movement is taking place. A "Film Library of Medicine" has been formed for the use of Medical Schools. Films are to be taken of all important operations. A special censorship has been arranged, and permission must be received before these films can be shown.

5. Some Legal Aspects of the Narcotic Drug Problem, with Particular Reference to Medical Practice.—Arthur D. Greenfield points out that the general scope and purpose of the Harrison Narcotic Law appears to be a regulation of the distribution of narcotic drugs, and the limiting of their consumption by human beings to cases where they are administered, prescribed or dispensed to a patient by a physician or dentist. Such regulation and limitation are not in themselves within the powers of Congress under the United States Constitution, but fall within the "police power" of the individual states. An attempt was made, therefore, to frame the act as a revenue measure and thus bring it within the power of Congress, which naturally led to grave doubts as to the constitutionality and construction of the law. Decisions were rendered in the cases of United States v. Doremus, and Webb et al. v. United States, when the court held the provisions of Section 2 to be constitutional, on the ground that the act was a revenue measure, and that the restrictions were germane to and legitimately incidental to the main purpose of raising revenue. The restrictions upon sales, in the opinion of the court, "tend to diminish the opportunity of unauthorized persons to obtain the drugs and sell them clandestinely without paying the tax imposed by the federal law." On the question of construction, it was held that exceptions A and B of Section 2 of the act did not permit the dispensing or prescribing of narcotic drugs to an addict where it was done neither for treatment of any disease nor in the course of professional treatment in the attempted cure of the habit. This construction was also based upon the supposition that an addict receiving a quantity of a drug might sell some to others without paying the tax. The author points out that the practical effect of these decisions is to deny to physicians the right to prescribe or dispense narcotic drugs to drug addicts except (1) when there is a legitimate medical reason for the use of the drugs, other than drug addiction, and (2) where the drugs are legitimately used in the course of bona fide professional treatment for the cure of the addiction. As there is still considerable room for doubt and misunderstanding, it is desirable that physicians should be informed of some of the questions likely to arise and the possible application of the decisions. It should be clearly understood that the Harrison Law is the paramount law and that State laws and regulations cannot alter, modify, or affect same; they may impose additional restrictions and requirements, which are binding within their jurisdiction, but, if less strict, cannot protect a physician complying wth them from prosecution under the federal law. In regard to actual medical treatment for the cure of addiction, there can be no doubt that the reduction treatment, or treatment in which the dose is maintained with other medication, during a period preparatory for actual withdrawal, may be legitimate under conditions in which the drug is administered by a physician or nurse, and the period of administration not unnecessarily prolonged. A more serious question arises, however, in considering the legal status of the "ambulatory" treatment when the drug is self-administered. It is generally conceded that this method is not usually successful, but it is contended that were the patient prevented from securing supplies elsewhere, the method would be successful and an attempt to put this into effect has been made in the city of New York. The legal principle that no physician is protected against federal prosecution by any local law or ruling must, however, be remembered in this connection. The question as to whether morphine may be prescribed for the maintenance of the comfort of the user has been answered in the negative in the case of Webb et al. v. United States. The author draws attention to the fact that though it cannot be said that the Supreme Court has definitely decided that "ambulatory" treatment, when given for the purpose of cure, is illegitimate, such a decision would be in harmony with the principles laid down in construing the Harrison Law, irrespective of the medical merits of the treatment or of any precautions taken to insure its curative efficacy, or the patient's access to other sources of supply, unless these were supplemented by adequate means of preventing the patient from disposing illegally of the drug. The use of narcotic drugs in the areatment of patients who are not drug addicts is not affected by the decisions in question; nor is their use in the treatment of other pathological conditions rendered illegal by the fact that the patient may be an addict. As a safeguard against federal prosecution, the safest plan, when the physician is not reasonably sure of the existence of an independent cause for treatment, is to administer the drug direct rather than prescribe or dispense same. Even though a physician might supply an addict with narcotics for the purpose of cure, honestly believing the "ambulatory" treatment to be a medically legitimate curative treatment, he might nevertheless be held guilty as doing an act contrary to the policy of the law, and he could not justify himself from the legal standpoint merely by proof of good faith, that is that he believed, from the medical standpoint, that the method was meritorious, or even by proof that it was meritorious, since there are other methods of curative treatment which are medically at least as sound, and which do not involve any act in conflict with the policy of the statute. The author adds that whereas Treasury Decision 2200, dated May 11, 1915, permitted the prescribing or dispensing of an amount of drug larger than that necessary to meet the immediate needs of the patient, provided the good faith of the physician was shown by a decreasing dose, in the case of treatment of an addict, a ruling issued July 2, 1919, revokes this and states that revocation shall be applicable in all cases, whether a decreasing dose is indicated or not.

4. Nephritis in the Soldier.—Reginald Fitz. See MEDICAL RECORD, xcvi, 2, 1919, p. 87.

6. Epigastric Hernia in the Soldier.—J. N. Hall draws attention to the importance of a careful examination for epigastric hernia in every case of digestive disease. He points out that perhaps in 80 per cent. of cases there are no symptoms and that these are

in general the cases in which no true omentocele exists. When there is an omentocele the symptoms are pain or troublesome discomfort, a feeling of dragging, and the ulcer syndrome, sour stomach, occasional nausea, even vomiting, distress after eating, with periodic exacerbation of all symptoms and even attacks of colic. As signs he mentions: bulging in the epigastrium; the fact that sharp pressure causes the patient to double up to escape the pain, with in some instances the "electric bell reaction" when a touch on the hernia causes instantaneous belching. The author is of opinion that the definite association between epigastric hernia and gastric ulcer is not recognized by internists as it should be. He points out that if a tender hernia is overlooked, the patient receives no benefit from operation for gastric ulcer, a probable explanation being that the long continued reflex irritation of the stomach by the omental drag is followed by hyperacidity and ulcer, as in chronic appendicitis. If a hernia is found, the opinion of a surgeon should be obtained as to the advisability of operation, unless it is clear that the hernia is without symptoms. These hernias are so minute in many cases that it may safely be said that the failure of the average physician to find them in possibly about 1 per cent. of the subjects examined is to be taken as evidence that the examination was made without sufficient care. Since less than a fourth of these hernias are associated with any digestive disorder, the question of operation arises in only a minority of cases; but it should, nevertheless, receive the most careful consideration. The surgical operation involved is trivial in comparison with the importance of the results commonly obtained.

1. The Cavendish Lecture on the Rôle of the Consulting Surgeon in War.—Sir George Makins states that he believes the subject of his lecture to be of prime importance to the future of both civil and military surgery and remarks that lessons derived from the experience of the South African War seem to have been lost sight of. Basing his remarks principally on the part of the campaign conducted in France and Flanders, the author takes up the duties of the consulting surgeon. He points out that these officers were first appointed in the South African War, when they were given a position of great dignity and freedom and treated with great monetary liberality, but had no actual military rank in the regular service. In the great war just over, the first consultants left to join the army in September, 1914, having been given suitable rank and considerable freedom of action, but with no defined duties. Though possessing no administrative position, there are numerous matters in the administration of the medical service in which the consulting surgeon can take part with advantage. He is interested in questions of location, construction and equipment of hospitals, and in the late war was frequently called upon for advice regarding the arrangement and equipment of special departments of hospitals, making a steady stand for the provision of huts or buildings in place of the marquees which proved so unsuited to the climate and the form of warfare. Demands for splints, apparatus, surgical instruments and various devices for treatment were all subjects which were fruitfully discussed between the consultants and the senior administrative officers. By reason of his knowledge and experience, the consultant is in a position to judge of a man's fitness to occupy a particular post and his advice is therefore of great value in the nomination of medical officers to fill special surgical posts. It is here and in the maintenance of the efficiency of the units that the consultant comes into contact with the administrator, and it is important that there should be mutual confidence and friendship. In this connection the value of meetings of the director-general, or the directors of medical services as the case may be, with the consultants as a body, for the discussion of matters in which administrative detail bears closely on medical treatment or vice versa and for the consideration of large questions affecting the general treatment of the patient, cannot be overestimated. The consultant may also do much to co-ordinate surgical work, to regularize and bring into conformity the work being carried on throughout the entire army. This is a most responsible duty, as care must be taken not to obstruct advance and at the same time avoid unnecessary changes. The consultant is in a position to exercise a strong influence for good; he may encourage individual medical officers to devote attention to a particular class of case or line of treatment and ensure that a proper supply of material is assigned to them, and in offering advice must be guided by the capacity and experience of the medical officer concerned. Moreover, he is in a position to bring recent discoveries and advances to the notice of medical officers, but he must be careful not to establish a dead level and thus interfere with the exercise of individuality. Not only may information be casually passed on during the daily round, but advantage should be taken of the medical meeting with its valuable opportunity for discussion. The schools of instruction established to assist the young officer unfamiliar with the class of work to be done or the conditions under which it must be performed, offer a further opportunity for instruction and many consultants have rendered valuable aid by delivering lectures, initiating discussions, and giving practical demonstrations. At a later date, similar schools were organized at the penultimate base, which would have been of the utmost value had it been possible to establish them at an earlier date. In the initiation and co-ordination of research the consultant has unusual opportunities, because it is within his power to arrange that a large number of cases should be placed under the charge of one officer, and thus make it possible to form an opinion as to the merit or demerit of a particular method. The author then takes up the question of the location of the consulting surgeon. In the late war the British surgeons worked on the concentric system, that is, one section was attached to the forward units and the other to the hospitals on the lines of communication. The French, on the other hand, followed the radial system, which possesses manifest advantages from the point of view of the consultant's duty as a "liaison officer." One great advantage of the system followed by the British was that the consultant became personally acquainted with all the medical officers within his area. Comparing the two systems, however, the author, both from observation of the work of the French consultants and from personal experience in the South African War, prefers the radial. In the British Army, after the initial period of the war, the two senior consulting surgeons were allotted a somewhat different position to the others, liaison duty being the chief feature of their work, and the author points out that if these officers, instead of retaining the concentric system, had worked radially, each over a definite area, a more satisfactory result might have been attained. He also mentions that by "the base" should be meant the actual base hospitals in England and not the general hospitals situated at the Channel ports, and adds that practical experience appears to demonstrate that a combination of the two systems may retain the advantages of both, the duties of one class of consultant

approximating to those of a line-of-communication officer, while the duties of the other would be confined to the definite area or army assigned to it. As regards the actual operative work, the consultant should be prepared to operate when required, but if he gives too much time to operating his more important duties may be restricted or interfered with. A consultant working on the radial lines would be principally concerned in co-ordination of methods and equipment and the diffusion of information, whereas one working on the concentric lines no doubt would feel that operative work formed a more important part of his function. As for literary work, the consultant probably follows the best course in confining his output to definite subjects and inciting others to place their experience on record; otherwise he incurs the risk of being thought to make use of the experience of others for his own benefit. Considering the mode of choice of consultants, Sir George points out the majority will probably always need to be recruited from the ranks of the civil profession, but that there is every reason to encourage officers of the regular service to qualify for these posts. The possibility of holding them offers a great inducement to such officers to give their main attention to strictly medical work and thus an escape might be possible from the unsatisfactory conditions under which administrative work offers the only road to highest positions in the service. The author also remarks that recent experience has shown that science as a bond between the nations is not sufficiently strong to withstand the forces set free by the outbreak of war between them, and the fact that the war has found the men of literature and science amongst the most active and polemical writers on either side, goes to show that the highest grade of mental cultivation has little influence on the elemental characters of man's nature. On the other hand, amongst the surgeons of the Allied nations an increased spirit of fraternity and intimate co-operation has flourished. In regard to the future status of the consulting surgeon, the author refers to the fact that the system evolved in the British Army has been founded upon usage during the war and has resulted from a process of development in successive steps and, therefore, is no doubt capable of further regularization and organization, and while there can be no doubt that the experience gained will be utilized by clearly defining the future status and duties of the consultant, these should be laid down while the facts that should decide them are still fresh in the minds of the powers that govern the Army Medical Service. It is much to be desired that the principle introduced in 1903 of inviting civil consultants to form a part of the staff of the Military Hospital at Millbank should undergo further development. He closes with an allusion to the charm of practising surgery for the sake of surgery alone, which is possible only in such a position as the consultant enjoys, and the pleasure of cultivating a close relationship with colleagues such as is impossible in civil life.

2. The Operative Treatment of Simple Enlargements and Tumors of the Thyroid Gland.—Claude Frankau considers the surgical treatment of simple enlargement of the thyroid gland by a review of fifty cases. Under the head of simple enlargement he includes the following cases: (a) Colloid goiter, a term which he prefers to parenchymatous goiter, since histologically the most marked change is increase of colloid with distension of the vesicles. A large proportion of the early "soft" cases are amenable to medical treatment, and operation should only be performed for definite symptoms or severe deformity, and for cosmetic reasons require careful consideration. The symptoms most commonly complained of are due to pressure on or dislocation of the trachea, a condition most likely to obtain if the goiter is asymmetrical or partly intrathoracic. Occasionally there is dysphagia. The more advanced cases of this type the author places in the next class. (b) Diffuse Adenoma. The pathology of this condition is a little obscure; some cases are definitely due to the presence of multiple small cystadenomata with little or no capsule to the growths, others appear to be result of fibrosis in a colloid goiter. The symptoms are nearly always those of dyspnea—especially at night and on exertion. The goiter in these cases grows to a very large size. Palliative treatment gives no relief, and operation is justifiable if the enlargement is marked, even if no symptoms are present. (c) Encapsulated cysts and solid adenomata. Of the 50 cases under discussion, 32 were of this type. The cysts are not infrequently multiple and may grow to a very large size. Usual symptoms are those of dyspnea; pain or dysphagia may occur, but are rare. Even if no symptoms are present, operation is advisable if the tumor is of any size, and particularly if it is situated in the isthmus. The most difficult and dangerous type of case is where the cyst is partly or completely retrosternal, when symptoms are much more severe and stridor may be marked. Any intercurrent respiratory diseases may easily be fatal, and in one of the author's cases sudden death from suffocation occurred as a result of hemorrhage into the cyst before operation could be performed. In five cases there was a history of rapid increase in size of the tumor with exacerbation of symptoms, due in every case to hemorrhage into the cyst. The author also points out the danger of serious obstruction to respiration during operation. (d) Inflammatory affections. Inflammation of the thyroid is not common and suppuration within the gland is even more rare, but three cases of abscess in the gland have come under the author's care, in one of which death occurred from edema of the larynx before operation could be performed. Commenting on the operations, Frankau points out that the anesthetic has rightly been considered one of the chief dangers in thyroid operations and for this reason local anesthesia has been advocated. He states that in all his cases he has been fortunate in having the assistance of highly skilled anesthetists, and that he has always used general inhalation anesthesia. The anesthesia should be comparatively light throughout, so that return to consciousness is rapid. He has found the low transverse collar incision most suitable in the majority of cases, as it gives good access and, if carefully sutured, a very good scar. However, in small cysts or adenomata of the isthmus, which are often more accessible through a median vertical incision, and where the goiter is large and there is extensive prolongation upward toward the angle of the jaw, he makes an exception. Incision should be free to avoid the necessity of strong retraction, and superficial veins should be clipped and ligatured as soon as exposed. The sternohyoid and sternothyroid muscles can readily be retracted inward and outward and may be divided if additional room is required; division of the sternomastoid is never necessary. The fascia over the gland is next cleared, the veins being picked up and ligatured. The gland in its capsule is then isolated and the upper and lower pedicles identified and freely exposed, a step which is essential whether enucleation or extirpation is contemplated. In an enucleation the true capsule of the gland is incised, bleeding points being clamped and ligatured at once; the gland is then divided and the tumor enucleated by gentle finger dissection. In the case of retrosternal cysts, the upper part of the cyst should be cleared as far as possible and enucleation commenced from below and behind. The head should be kept raised so as to relax the trachea. In extirpation the vessels entering the upper pole of the gland should first be exposed and ligatured; the middle thyroid veins are then clamped and divided and the gland turned downward and inward so as to expose the inferior pedicle, which is ligatured through thyroid tissue. In cases of hemithyroidectomy, the author removes the entire isthmus, checking bleeding by figure of eight stitch. Drainage is required in all cases to avoid the formation of hematoma, which in addition to the prejudicial effect

on healing may cause dangerous respiratory embarrassment from pressure on or kinking of the trachea. The author's experience has been that a ¾-inch soft walled rubber tube with one side perforation near the end is the best. Suture of the incision should be in layers—that is, platysma and skin separately. A very abundant gauze dressing should be used, over which a pad of wool is applied and the whole fixed by a double figure-of-eight bandage, and in order to prevent infection by vomited material the upper edge of the dressing should be sealed down by collodion. As to complications and sequelae, severe bronchitis ensued in three cases of the series, wound haematoma occurred in four cases through using too small a drainage tube, and a persistent mucous fistula occurred in one case after enucleation of a cyst, due probably to a mild degree of sepsis.

1. A Few Derogatory Remarks Concerning the Inhalation Treatment in Pulmonary Tuberculosis.—Albert C. Geyser's theory of the causation of phthisis, i.e., that the bacillus of Koch has very little trouble in the invasion. Frequently this bacillus enters the body during the prenatal period of the individual. He is convinced that 90 per cent. of all phthisis has its inception in ulcers. The other 10 per cent. may have contracted the infection. The mere entrance of the bacilli into the tissues does not produce phthisis. Most of the bacilli that enter the body are quickly destroyed the moment they come into contact with the blood of the individual. The bacillus of Koch cannot live long in live human blood. If the bacillus after entering the system multiplies, it is a sure sign that somewhere in the body it has found a bloodless area. Anemia is a prime requisite for the future existence, multiplication and propagation of this germ. Anything that will prevent malaria will prevent phthisis. The prevention of anemia is the only real, natural physiologic system of prophylaxis. After phthisis has occurred the conditions have changed. The bacillus by itself is quite harmless, billions could and perhaps do invade the body of the average human being. The bacilli themselves have never killed anybody. It is a certain toxic substance, the result of the metabolic processes, that does the poisoning. The metabolism of the bacillus cannot take place without a pre-existing anemic area. In order to insure the continued existence of the bacillus, it furnishes the toxic material which in turn causes a localized blanching; hence the anemia.

All the antiseptics, creosote, camphor, phenol, gomenol, iodoform and turpentine, when inhaled in a volatilized state enter with the air current. There is no doubt that such a "medicated" air mixes with the blood and that it is carried to all parts of the body. All of these antiseptics are foreign to the physiology of the economy. Since they are foreign bodies the system reacts to them. If this reaction is one of generalized hyperemia it is at least logical to account for the "prompt general improvement, increased appetite, gain in weight, etc." In other words, the antiseptics as such play but minor parts, but the reaction to such an irritant, when inhaled for an hour daily, may remove the first requisite, namely, the anemia. When the anemia is thus overcome, bacilli fail to multiply, the protein toxic element emanating from the germ is no longer produced, hence corresponding improvement in the condition of the patient.

Geyser says that for ten years he has demonstrated that blood, normal blood, and plenty of it in the lungs leads to a recovery where recovery is still possible. If diathermia is applied to the regions of the lungs for one hour or more daily, the patient put upon a suitable diet, rich in lime salts, proper rest and hygiene are carried out, many cases of phthisis will make a permanent recovery.

Le Progrès Médical.

April 12, 1919.

Retrospect on the Grippe.—Chalier wishes to avoid the beaten track in the present article and simply gives his opinion on certain moot features. Up to September, 1918, the author had seen only benign cases—benign yet spectacular, setting in with dramatic abruptness and attacking the strongest and most resistent. But this abruptness and severity connoted a brief course and rapid recovery. In two or three days it was all over, and complications as good as absent. Now by October first the picture changes—not entirely nor all at once, but there was noted a greater duration and a tendency to complication involving a third of all smitten. There was in other words a mixture of mild and severe cases. Characteristic of the second wave was the tendency to nosebleed and other hemorrhages, which in women included metrorrhagia. The pulse did not follow the temperature. This dissociation between pulse and temperature is as common in grippe as in typhoid. The author goes quite extensively into the differences between typhoid and grippe, as shown by a study of the pulse and temperature and fever curve. Cyanosis is a most valuable symptom and when it affects the terminal structures, as the nails, it suggests pulmonary or cardiac implication and is hence a bad prognostic. It is so vital that we might speak of the entire condition as a recoverable or irrecoverable cyanosis. In the routine examination we should never neglect to make the patient cough before taking his sputum. It is strange that this routine measure is so often neglected in our grippe investigations. In regard to the third of cases which were complicated, the usual digestive and nervous types are so uncommon that they may be neglected. The complications to be dreaded are extreme congestion or suppuration of the lungs, edema of the lungs and other lesions which provoke cyanosis, including of course pneumonia. In regard to treatment the author regards quinine as almost a specific for the malady, however given.

Correspondenz-Blatt für Schweizer Aerzte.

April 26, 1919.

New Ideas in Goiter Prophylaxis.—Klinger calls attention to inactivity along this line in recent years, a state of affairs much aggravated by the pandemic and the war. The attempts made in this direction have comprised the use of minute doses of iodine and the similar exhibition of quinine and silica. The Swiss temper has not invited a comprehensive plan of popular compulsory hygiene. In America something of the latter type has been tried out by Marine who gave two brief annual courses of sodium iodide to 1000 school girls with proper controls. It had been determined in advance that 56 per cent. of school children had some enlargement of the thyroid. The experiment was conducted in a locality in which goiter was endemic. The prophylactic experiment was supplemented by a similar plan of treatment of existing cases. The results, so far as treatment is concerned, showed that iodine has considerable power in the arrest and improvement of enlarged thyroid and that not a single case of Basedow syndrome was set up. Marine's work has shown that in all probability a similar simple wholesale campaign in a country like Switzerland would result in the prevention of much goiter. Fewer operations would be necessary and children's school attendance would not be interrupted. The problem is eminently one to be settled in school years. The teachers could be used to administer the syrup of sodium iodide (one is grotesquely reminded of the "brimstone and molasses" given to the pupils of "Dotheboys Hall"). The school physician would, of course, be the responsible agent for the treatment. A good system of records would have to be kept and this would entail some expense. Preparations to ward off all danger from careless administration would be necessary, for a few cases of iodism or hyperthyroidism might nullify the entire campaign.

Book Reviews.

THE OXFORD MEDICINE. Edited by HENRY A. CHRISTIAN and SIR JAMES MACKENZIE. Volume I. Part 2 and 3. New York: Oxford University Press, American Branch.

THE contents of the second part of Oxford Medicine are a chapter on pathological physiology and its relation to internal medicine by Albion Walter Hewlett and one on hydrotherapy by Guy Hinsdale. Both of these writers are acknowledged masters of their subjects and it only remains to be said that the contributions are fully worthy of their reputations.

To the third part Sir William Osler contributes an article on the treatment of disease pointing out how conceptions as to the nature and consequently the treatment of disease have changed with the passage of time. For long centuries disease was believed to be the direct outcome of sin and the treatment was simple, a readjustment in some way of man's relation with the invisible powers, malign or benign, which had inflicted the scourge. From Hippocrates to Hunter the treatment of disease was one long traffic in hypotheses. It is only in the past fifty years that our conception of the nature of disease has been revolutionized, and with a recognition that its ultimate processes, whether produced by external agents or the result of modifications in the normal metabolism, are chemico-physical, a standpoint has been reached from which to approach the problems of prevention or cure in a rational way. For instance, a fuller knowledge of etiology has led to a return to methods which have for their object, not so much the combating of the disease germ or of its products, as the rendering of conditions in the body unfavorable for its propagation and action. In diet, exercise, massage, and hydrotherapy we are every day finding out the enormous importance of measures which too often have been used with greatest skill by those outside or on the edge of the profession. Lastly, we have advanced firmly along a new road in the treatment of diseases due to specific microorganisms, with the toxic products of which we are learning to cope successfully.

Another paper of value in this number is that by John J. Mackenzie dealing with the living causes of disease and how they act. The infectious diseases brought about by living organisms, belonging to both the plant and animal kingdoms are described as well as the manner in which the infecting agents gain access to the human system.

UNIVERSITY OF IOWA STUDIES IN MEDICINE. Volume I. Number 5. January, 1919. Price 40 cents. Iowa City: Published by the University.

NUMBER five of these studies contains reprints of sixteen articles which appeared, for the most part in Journals, during the last half of 1918. The titles are those of subjects scattered widely through the field of Medicine and are representative of the activity at this institution.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Reprints, Volume XXX. Price $2.00. New York, 1919.

THIS volume of Studies contains reprints of forty-six articles which have appeared recently. They are grouped under the headings Pathology and Bacteriology, Physiology and Pharmacology, Chemistry, Experimental Biology, Animal Pathology and The Hospital of the Rockefeller Institute. While many of the articles are, in themselves, of very limited interest they have their importance in their special fields. These volumes of Studies which appear at frequent intervals constitute a valuable collection of articles on research.

COLLECTED REPRINTS FROM THE GEORGE WILLIAMS HOOPER FOUNDATION FOR MEDICAL RESEARCH. The Department of Research Medicine of the University of California Medical School, San Francisco. Volume III. 1917-1918.

THERE are reprints of thirty-five articles in this volume chiefly upon physiological subjects. The most important is perhaps the table PH, H^+ and OH^- values with which is included a very extensive bibliography, by Schmidt and Hoagland. This article had not been previously published in a journal.

THE SOLDIER'S HEART AND THE EFFORT SYNDROME. By THOMAS LEWIS, M.D., F.R.C.P., F.R.S., D.Sc., Physician of the Staff of the Medical Research Committee; Consulting Physician in Diseases of the Heart, Eastern Command; Assistant Physician and Lecturer in Cardiac Pathology, University College Hospital, London. Price $2.25. New York: Paul B. Hoeber, 1919.

DR. LEWIS wrote this book primarily as a war book, to supply information regarding heart affection, and the best methods of detecting such complaints when examining men for the army. The book is full of valuable hints for examiners and should prove of almost as much use in civil as in military life.

TRICHOMONOSIS INTESTINAL. By DR. EDMUNDO ESCOMEL, de Arequipa, Peru. Miembro de la Academia de Medicina de Lima. Anales de Facultad de Medicina. Montevideo, 1918.

THE views of Dr. Escomel have repeatedly appeared in print upon this subject of trichomonosis. They have been reviewed in the columns of the MEDICAL RECORD and the *Lancet*. The author has presented his thesis very lucidly and it should be well known that certain intestinal parasites (protozoa) may cause the phenomena of dysentery, which thereby is shown to be at times of autochthonous origin.

DIET IN HEALTH AND DISEASE. By JULIUS FRIEDENWALD, M.D., Professor of Gastro-Enterology in the University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore, and JOHN RUHRÄH, M.D., Professor of Diseases of Children in the University School of Medicine and College of Physicians and Surgeons, Baltimore. Fifth Edition Reset. Price $6. Philadelphia and London: W. B. Saunders Company, 1919.

THIS work by Friedenwald and Ruhräh is so well and favorably known that there is little to add to what has been said before except that this edition has been thoroughly revised. A good deal of the volume has been rewritten in part or entirely, including the sections on infant feeding, rectal feeding, diabetes, obesity, acidosis, the Karell cure, renal diseases, and pellagra and the deficiency diseases. The endeavor has been to bring together in as small a space as possible, knowledge of the present day scientific dietetics. In this effort the authors have succeeded.

UNIVERSITY OF MICHIGAN, CONTRIBUTIONS FROM THE PATHOLOGICAL LABORATORY. Researches on the Pathology of Mustard Gas (Dichlorethylsulphide) Poisoning. By ALDRED SCOTT WARTHIN, Ph.D., M.D., Professor and Director, and CARL VERNON WELLER, M.S., M.D., Assistant Professor. Vol. IX, 1918-1919. Ann Arbor, Michigan.

THIS volume is a reprint of the six articles on this subject which have appeared in the *Journal of Laboratory and Clinical Medicine* during the past few months. The skin, ocular and respiratory, and gastrointestinal tract lesions are discussed separately and are followed by a study of the general pathology. An article on the clinical pathology and one on treatment close the collection. It is an extensive study, carefully and thoroughly carried out, and adorned with many excellent illustrations. A brief bibliography is appended.

THE CONTROL OF HOOKWORM DISEASE BY THE INSTITUTE METHOD. By H. H. HOWARD, M.D., Director for the West Indies. Publication No. 8. The Rockefeller Foundation, International Health Board, New York York City, 1919.

THIS publication presents the general procedure followed in conducting any demonstration against hookworm disease by the intensive method, with all the information necessary to permit the adoption of this plan. The very excellent results which have been obtained in the West Indies during the years 1914-1917 are the justification for the plan adopted and it is difficult to believe the results obtained could be bettered. The report is very interesting reading and will be of value to anyone having to do with this work.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Seventieth Annual Session Held at Atlantic City, N. J., June 9, 10, 11, 12, and 13, 1919.

(Special Report to the MEDICAL RECORD.)

(*Continued from page* 176.)

SECTION ON MISCELLANEOUS TOPICS.

Wednesday, June 11.

DR. H. E. MOCK OF CHICAGO IN THE CHAIR.

Preventive Surgery as Demonstrated by Industrial Practice.—Dr. WM. J. CLARKE of Worcester, Mass., made this presentation. This type of work naturally differed from war surgery, although the treatment of accidental wounds and of foreign bodies came under observation. The industrial surgeon for instance was often called upon to treat cases of foreign bodies in the eye. Thorough cocainization was essential, and very often the use of the cataract knife. For the subsequent irritation a weak argyrol solution was used. One of the most vital problems that came before the industrial surgeon was the treatment and repair of hernia. The question arose "Was this to be classed as an industrial accident?" The sac was often congenital, and there was also a racial susceptibility. The question of why hernias recurred was a physiological one. One often saw a sac adherent to the cord, the neck was small, and after amputation of the sac, the repair appeared to be without a flaw; yet, 6 months later, the man came back with recurrent hernia. It was essential that man with a definite bulge should not be put to do heavy work.

Dr. W. S. SHERMAN of Pittsburgh said that 10 years ago the industrial hospital was poorly equipped and the surgeon often careless as to asepsis. Employers had now come to realize the importance of keeping their workers fit, and the immense loss entailed to industry by illness. A standardization of the best methods of technique was necessary. An efficient cleansing of the wound and soft parts was essential, with debridement of devitalized tissues. Bichloride could be used as a wet dressing. Much had been heard of dichloramine-T, but it had often proved a failure. The injuries received in the steel mills were often sterile as coal, coke, and iron did not produce infection. Dakin's hypochlorite solution, used according to the Carrel technique had been found a useful solvent of necrotic tissue which could be easily removed. Industrial surgery was naturally of a different type from war surgery. Industrial surgery and medicine were being put on a higher plane than they had yet been, and the plant managers were beginning to interest the best elements of the profession.

Dr. O. P. GEIER of Cincinnati said that the industrial surgeon might stimulate the patient to have necessary work done by the outside surgeon; thus in cases of neoplasm or appendicitis, for instance, he could give very necessary advice. This was one of the contributions that he could make.

Dr. HARRY E. MOCK of Chicago said that the timely examination and removal of diseased tonsils might save complications of appendicitis and gall-bladder invasion, as well as rheumatism. This was one side of industrial prevention. Surgical judgment in treatment and closing of wounds was required. Deformities could be treated and prevented. The treatment of severe injuries, so as to know when to use surgical intervention to avoid shock and hemorrhage was an important duty of the industrial surgeon.

Dr. J. W. SCHERESCHEWSKY of Washington, D. C., in discussing the physiology of hernia, said that it would be presumptuous of him to answer such a difficult question in full, but the result of his personal experience led him to believe that intraabdominal pressure was the result of opposition to contraction of abdominal muscles. There were two opposed schools of belief. One said that hernia was a congenital defect and that occupation had nothing to do with it. The other that stress and strain were the etiological factors. The truth lay somewhere between these two extremes. There was an incidence of hernias among those of sedentary occupation, and the development of musculature had much to do with the prevention of hernia and its recurrence. The chief factor seemed to be that if the abdominal pressure was equally balanced on all sides, the hernia could not recur, but if one had thin musculature, tendons, and fasciæ, which did not produce sufficient counter pressure, it seemed inevitable that protrusion must occur. If the abdominal wall after repair retained the same state of innervation with consequent muscular tonus, the hernia would remain cured, but with impaired tonus recurrence must take place.

Dr. W. J. CLARKE, in closing, said that the care and cure of hernia was one of the most vital industrial problems. Another important point was the care of the wound, to take care of it mechanically and chemically so that it would remain clean. Dressings must be aseptic; instruments and technique must be perfect.

Industrial Medical Practice and Sickness Prevention as a Factor in Public Health.—Dr. C. E. FORD of New York presented this topic. The speaker said that some years ago the employment of a physician was regarded as benevolence on the part of the employer. The economic value of the health of the employee had not been recognized. It was now beginning to be understood that industry would best be benefited by the employment of qualified physicians. Part time service of industrial physicians was of little use. Men best qualified to undertake this work were those with at least five years general practice, experience in health department work, and in dispensary work to acquire the social view point. Varied branches of knowledge were helpful, such as recreation; accident prevention; pension and insurance knowledge; plant organization; employment methods; physical and mental disease; wages in relation to cost of living; hours of work; shift systems; rest; absenteeism; labor saving improvements; old age; physical working conditions; industrial sanitation; examination of employees; community sanitation; housing; follow-up work; transference of misfits; athletic activities; operation of hospitals; raising living conditions. An interest in and comprehension of such topics would so fit a man that he would find his post seeking him. Social service departments had done much to extend this field by lectures and public health instruction. The method of presentation to the worker was of the greatest importance. Pay roll slips could be used and were often welcomed by the employees; moving pictures played an important part; the analogy between the machine and the human body could be pointed out; personal hygiene could be taught. Sanitation, nuisances, garbage disposal, sewage disposal, flies, housing, prevention of infection were all subjects of great educational importance. The frank discussion of venereal disease and its prevention, the control of tuberculosis, the necessity of rest, the medical examination of school children, were all matters of vital interest. Many Government Departments and National Associations provided educational films now at a very moderate cost and of great educational value. In a survey of the funds spent by 99 leading industries, it was found that $2.50 per capita was the rate expended. If industry found it paid to spend this sum, then surely health departments could afford to appropriate a like amount in the public health service.

Dr. W. A. SAWYER of Philadelphia said that the physician in industry was a public health factor. There were approximately 30 million industrial workers, in the United States, *i. e.*, one-third of the population. Thus to reach industrial America with a health message was to leaven the whole. The industrial doctor was an educator to the entire man. He should encourage wholesome living and clean thinking. One could not superimpose a real education, while neglecting the factor of the soul. The whole man was body, soul, and spirit, with strong emphasis on the spirit. Man must be made physically fit so that he could reach forward to the higher functions of the spirit. Dr. Cabot's book "What men live by" was an illuminating work. However, collectivism came from perfected individualism. Hygienic, orderly work would be an inspiration to everyone and as soon as the individual had a clean place to work in he wanted a clean place to live in, the example being sufficient to lead him in the right direction. Industrial medicine served to reach a class that could be reached

by no other means and there should be full cooperation between public health workers and industrial physicians. Politics had unfortunately handicapped public health work, and health officers felt this themselves, for many of them were imbued with the desire to make the world a better place to live in. The inalienable right of every man, woman, and child to happiness was being felt and would lead to great future accomplishments.

Dr. D. L. EDSALL of Boston said that the interest he felt in industrial disease was from the standpoint of general medicine, but he felt that industrial medicine was one of the largest factors in relation to public health. At the Massachusetts General Hospital a general survey was being made of patients who came to the occupational clinic, with a view to seeing if their occupation had anything to do with their impairment of health. In five thousand people it was found that occupation had something to do with it. If thirty millions of workers were employed in this country, then according to these figures (one-tenth of this number) at least three million people would be affected by occupational conditions. They had heard that the average industrial worker lost 8 days in the year from sickness; what an enormous amount of time this represented when considering workers as a whole! The industrial physician was in the strategical position of greatest advantage to get into close touch with the worker and exert great influence in organization. The war had shown what organization could do and its power to improve the health of the people. The opportunity for community service by the industrial physician was illimitable.

Dr. H. MOCK of Chicago said that many industrial organizations had overworked physicians without sufficient number of assistants. The results in these cases were very far from ideal. He had found it a good plan in Chicago to offer good men good salaries to work three and a half hours a day, and allow them to devote their other time to practice and research. In this way several good men could be called in. The time was covered and plenty of assistance and better service was rendered than with too few full-time men.

Dr. C. HASTINGS of Toronto said he must express his surprise that this measure which had brought so much advantage to community hygiene should have been neglected for so long. Four years ago they established a department of industrial hygiene in Toronto, and expected that they were starting considerable trouble, but in less than twelve months they were receiving letters expressing appreciation of the plant owners for the valuable assistance rendered. Employers of labor were waking up and it was only necessary to get at these men through their pockets and show them that a loss of 10 to 15 per cent. of efficiency in the employee was a serious economic loss, and they would be willing to put in good ventilation or any other improvement. It was easy to persuade them that one was a friend if one saved money for them. For the past few years municipalities had been taking up the subject of hygiene in schools and by process of evolution public health had to start where eugenics stopped. Where nature failed, nurture had to step in, so that medical care should not leave off at school, but follow the individual in his industrial career.

Dr. H. MOCK of Chicago said that Canada had taught us lessons in rehabilitation of soldiers, and would most likely do so in industrial hygiene.

Dr. O. P. GEIER of Cincinnati said that a problem was how the health officer could be serviceable to the community at large. He was apt to see mass problems instead of individuals. The industrial physician could be of use in bringing the instruction to the individual. How much the industrial officer could be helped by the health officer had to be determined, and how much health departments could be helped by industry in the control of morbidity would be seen. In the epidemic, industrial physicians had done much toward control, and the workers carried the word to their families. Industrial physicians should be under the control of the municipal and state departments.

Dr. HUBBARD of New York said that problems of municipal departments of hygiene was being considered in New York. The department had been interested in industrial hygiene since 1914. The number of physicians and instructors had been increased and many industrial questions had been dealt with. For instance in the Bush Terminal stores, Brooklyn, 35,000 people passed through daily. There were many nuisances, due chiefly to ignorance of the workers. Lectures were established and very good results had been obtained. Instead of two thousand nuisances, there were less than one hundred. The lectures were short, 5 minutes music to draw the people, 15 minutes talk, or moving pictures. Hand bills and circulars had been tried, but lectures to small groups seemed the best way to solve the problem. In regard to trades, the millinery trade for example presented 17 different kinds of industrial hazards and at least 28,000 people were employed.

Dr. AUGUSTUS WADSWORTH of Albany, N. Y., said that he was in touch with the laboratory side of the public health work. The laboratory was an important side of this work. He thought that industrial physicians should avail themselves more of the facilities offered by the State for laboratory examinations. Systematic examinations, especially in the venereal diseases would be of great industrial service. Appropriations at present were limited, but if a demand for the work arose there was no doubt that the legislature would see fit to appropriate the proper funds.

Dr. O. L. KIEFFER of Detroit said that if public health departments did not wake up they would be forced to take this work. Industrial medicine having engaged well trained men, will open the eyes of the employer to the need of better public health work. The employee would ask for better public health care, and the department would ask for more appropriations. With the employer and employee back of him the public health man had practically the community back of him.

The Enlarged Program of the U. S. Public Health Service, Division of Industrial Hygiene and Medicine.—Dr. SCHERESCHEWSKY of Washington said that they had learned where protection was weak. The epidemic of influenza found them without protective measures. The work of industrial hygiene was getting to have the greatest significance. The government was interested in enlarging it. People, however, thought that federal control could do things that it could not. The Constitution of the United States limited the function of the federal government. Health regulation depended upon powers within the States as well as upon the federal authorities. Federal legislation had to do with disease through maritime ports and interstate channels. Further than this questions had to be decided by State and municipal authorities. The federal government was the greatest advisory and investigating authority and cooperated with local health authorities in maintaining sanitary conditions. It contributed sums of money managed by the State towards farm, roads, and rural sanitation. Federal management of industrial medicine had been planned along the following lines: (1) extension of health service in industries to determine the extent and means of correcting health hazards; (2) development of an adequate system of medical and surgical supervision of employees; (3) securing adequate reports of the prevalence of disease among employees and sanitary conditions in industrial communities; (4) establishment of minimum standards of industrial hygiene and prevention of occupational diseases; (5) improvement of sanitation of industrial communities by cooperating with State and local health authorities and other agencies; (6) medical and sanitary supervision by the Public Health Service of industrial establishments owned or operated by the government. It could be said that if one-third of the life of the employee was spent in labor he should not be subjected to conditions inimical to health. The employee was a taxpayer and had a voice in health conditions of his locality. It was in his power to raise the sanitation in his community. A specific beginning had been made in the right direction. The Labor Department had established working conditions for the safety of the worker, under supervision of the public health service. Adequate preparations were being made, but the work being of a specialized nature needed a highly trained personnel, and organization must be made to spend money intelligently. This year five hundred thousand dollars had been appropriated, and one did not know as yet how that would be disbursed. Although general economy in public funds was desirable, the public health was not a subject upon which the State should economize. The plans, however, were made and even if money was not forth-

coming, there would be only a temporary lull. The workers were ready to go on with the plan.

The Efficacy of Measures for the Prevention of Disease.—Dr. GEORGE A. SOPER, Sanitary Corps, U. S. Army, presented this paper. The speaker said that in the control of disease, progress had been greatest in respect of the enteric and epidemic kinds and least of the respiratory and endemic types. The reason for this lay in the fact that of the three great lines of effort, namely sanitation, public health administration, and personal precautions, only the first two had been developed to a commendable state of efficiency. It could be said that respiratory infections were ten times as numerous as the exanthemata. The curve of pneumonia did not decline and no means of controlling it had been discovered. Personal precautions were the largest factor in this question; these included precautions of persons exposed, and precautions of the infected person. Precautions included isolation of the infectious sick and proper quarantine measures. In cities the prevention of disease depended upon many factors and was the result of collective effort. Proper supervision of food, of housing, of trades, of lighting, of water supply, of garbage, of sewage, all were important factors. In rural communities many of these measures were unknown. One of the lessons of the war could be applied to communities. This was that sources of infection should be sought out and prevented, not waiting for the time when infections would appear of themselves. Disinfection had come to take a secondary place. Proper ventilation and a high standard of cleanliness had been found of first importance. The soldier had been taught how to take care of himself. In regard to respiratory infections, the time to study the attack was before it appeared and made the application of the knowledge necessary. This disease was a reflection on common sense. It was for the individual to learn that the lessons of the army were not for the army alone, but to be appropriated by the whole world in times of peace.

Colonel KRAMER of the U. S. Army, said he had been associated with Colonel Soper in Public Health work. He felt that unless the medical profession approached this subject in a more scientific and thorough manner, they would be likely to lose control altogether, as the work was being done most efficiently by sanitary engineers.

Dr. A. E. CHASE of Texarkana said that if the departments of health were going to take over the work, he did not know how some people would be reached. A man in his part of the country might be born, live, suffer all the regular diseases, marry, bring up children, and die, without anyone being the wiser. He thought this work would be somewhat unwieldy in the hands of health departments.

Dr. NORTON of Philadelphia said that every college should have a course of sanitary engineering and that hygiene should be driven into students before they were admitted to practise medicine.

Dr. LARKIN of Buffalo said he did not know how it was possible to live up to the ideals of Dr. Ford. Medicine had become such a complex subject that it was hardly possible for one man to encompass all its branches.

Dr. C. HASTINGS of Toronto said that a great part of the work thrust upon boards of health had nothing to do with saving of life or prevention of disease. He thought that if the work were concentrated on these two problems it would not become too unwieldy to handle.

Dr. W. O. SMITH of Alameda, Cal., said that smaller communities suffered greatly from having only part-time health officers. This condition should be remedied. He always hoped to take back something from these meetings to be of help to his community.

Dr. C. P. SHELBY of Toledo, Ohio, said that he had been a health officer and now was in industrial work. Both sides should cooperate to help the other. The industrial had better opportunities of making friends with the workers; the health officer of supervising vital statistics and industrial hygiene.

Dr. L. I. HARRIS of New York said it was a pity that after these enthusiastic meetings nothing was done. Resolutions ought to follow the matters discussed, and the advice obtained carried out.

Dr. SCHERESCHEWSKY said that the responsibility rested with the community itself. The State and national boards were there for guidance and control. The individual citizen must play his part in demanding the best conditions.

Dr. SOPER, in closing, said that he appreciated the lively and full discussion, but he was disappointed that his points had not been more criticised, as he felt sure that some were weak. It was a pity that boards of health were not more generally distributed. It was known that only about 70 per cent. of the population were included in vital statistics. Dr. Wadsworth had made an interesting point in regard to State laboratory facilities. All groups should work together as harmoniously as possible. It seemed as if industry were teaching the health officer his job in many cases. The management of infectious diseases should be taught and emphasis laid on simple essential things such as light, air, and ventilation.

JOINT MEETING OF THE SECTIONS ON MEDICINE, PATHOLOGY AND PHYSIOLOGY, PHARMACOLOGY AND THERAPEUTICS, AND PREVENTIVE MEDICINE AND PUBLIC HEALTH.

Friday, June 13.

Experiments by Volunteers to Determine the Mode of Spreading Influenza.—Dr. M. J. ROSENAU of Boston presented this topic. A set of experiments were carried out on volunteers who were enlisted men in the U. S. Navy stationed at Deer Island. The work was under the combined auspices of the U. S. Navy and the U. S. Public Health Service. The volunteers were young men of susceptible age, and of good physical health, most of them never having had influenza. A few who had had the disease were studied in regard to possible immunity. A pure culture of the Pfeiffer bacillus was instilled into the nostrils of the volunteers and preliminary trials proved negative. A large quantity of a mixture of 13 strains of the Pfeiffer B. (some from autopsied lungs) was then administered. Next a suspension of the live organism containing several billion was sprayed into the nose, eyes, and throat on full inspiration. No sickness resulted. In the following experiment material from actual cases of the disease was taken, from bronchi, nose and throat, placed in salt solution and transferred with swab applicators onto the mucous membrane of nose, throat, and eye of the volunteers. None of these took sick. The next trial was with material taken from persons sick in hospital at the height of the outbreak. This failed to cause infection, and it was thought that the time of transmission (4 hours) might have destroyed a frail virus, and another attempt was made in which after 1 hour and 40 minutes the material from hospital patients was received by the volunteers. None of these took sick. It was then supposed that the salt solution destroyed the virus so that this factor was eliminated and material was transferred direct from nose to nose and throat to throat, using material from the tonsils and naso-pharynx of the infected. Nineteen volunteers undertook this experiment, some of whom had had the disease earlier. None of the nineteen took sick. These men were isolated for one week and then blood injections were made; 20 c. c. from the arm vein was taken from cases in the febrile stage and injected subcutaneously into the volunteers. Next muco-purulent material from the respiratory tract was injected into ten volunteers, by the subcutaneous route. No illness resulted. Next human contact was tried. Ten of the volunteers were brought into a ward of 30 beds filled with influenza cases. Ten patients were selected to be donors. The volunteers sat down by the bedside, talked five minutes with the patients; the patient was instructed to exhale as hard as he could, while the volunteer inspired his breath. This was repeated five times. The patient then coughed directly into the face of the volunteer five times. The volunteers then changed places and came into contact with ten different cases of influenza. Although the men carried out the experiments most faithfully and were inspired by idealism in their task, none of them received the smallest effect. It was perplexing what to do next. In February 50 volunteers offered for a new set of ex-

periments when the outbreak was on the wane. The Portsmouth Naval Prison was chosen for the next set of experiments. In this experiment in 36 hours 19 of the volunteers came down with fever, and sore throat, caused by hemolytic streptococci, a true septic sore throat, of which scattered cases had been noted in the prison. None of the donors, however, had septic sore throat. It was supposed therefore that the disease had been smouldering in the prison, and was transferred to the volunteers. Finally one doctor, who had been collecting material from healthy men in the navy yard, who were suspected of influenza but did not subsequently develop it, came down with the disease. It would seem therefore as if one should be very careful in drawing conclusions from such purely negative results. The volunteers might have been immune, or they might not be susceptible. Any attempt to transfer the virus seemed to have failed. Perhaps there are unknown factors and if anything was learned it was that nothing is known of the mode of transmission of the disease.

Epidemiology of Influenza.—Dr. WADE H. FROST of Washington, D. C., presented this branch of the subject. This disease, he said, was one of large features—great cycles of outbreaks, alternating with periods of comparative quiescence. A whole cycle of thirty years had been noted. Even during outbreaks, however, records had been poor and were often lost, so that between whiles the disease was confused with others. Mortality statistics in regard to influenza were unsatisfactory; in the intervals between outbreaks, deaths were registered for miscellaneous causes, and mortality statistics for the whole group would represent pneumonia plus influenza. In March and April, 1918, there was a rise in the pneumonia curve; this spread from East, to South, and West, and took about 4 weeks to cross the entire country. The extensive outbreaks were on the Atlantic and Pacific coasts and the milder ones in the interior. Twenty-eight per cent. was the average for all cities; 5-14 years was the age of highest incidence; females were more affected than males; and whites more than negroes. Case mortality, however, was higher in males than females. The one-year period, the 25 to 29 year period, and the period of old age showed the highest mortality. Towns with most cases did not have the most deaths, but there was no definite evidence of immunity noted. Judging from past years one might be prepared for disturbance of the pneumonia curve for some years, and the profession should be armed with the best methods of treatment and investigation. The only real way to prevent the disease was by a general immunization and it was necessary now to start on a long-continued and intensive study of the whole group of pneumonia and influenza infections. It was worth while the careful attention of clinicians to differentiate influenza better than heretofore and it was to be hoped that the profession would assemble records for the next thirty-year period.

The Bacteriology of Influenza and Its Complications.—Dr. WILLIAM H. PARK of New York presented this phase of the topic. The speaker said it was interesting to look over the records of former epidemics. European observers had isolated pneumococci, streptococci and other organisms as the main invaders. Pfeiffer then found a new bacillus and he assumed that this influenza (or Pfeiffer) bacillus was the pathogenic factor in the epidemic of 1889-90. It was found that other diseases, as measles, had the bacilli, but measles was proved to have nothing to do with the primary disease. Clinicians, bacteriologists and pathologists, however, assumed that the epidemic was the same and that the bacillus of Pfeiffer was the cause. Some observed the bacillus in many cases, and some in few. Some found streptococci, staphylococci, and pneumococci, and the mass of evidence became very confusing. At the time of the present epidemic laboratory workers were overwhelmed with war work, but efforts were made to find the cause. Some years ago Dr. Hess had made careful attempts to transmit chicken pox in ways which one would have thought would have succeeded, and yet he failed, so that it is proved that one has much to learn about the infections. One thing was known, that was, that in America the epidemic was one, and due to a single cause, for if not, then it was not one epidemic, but a coincidence of various epidemics. If the same organism could be found, the cause of the epidemic had been found. Different views, however, were held by different investigators, and the majority concluded that they had not found the organism, the minority that they had. The influenza bacillus was considered the most probable invader. A few maintained that a filterable virus was present in a few cases, but before the epidemic a filterable virus had also been found as the cause of common colds. Another point was that bacteriologists had to be trained to find the influenza bacillus; a definite technic was needed. No one single strain could be found; they were divided into groups, as were the pneumococci. Dr. Williams got 150 strains from different cases. In studies on immunization of rabbits, the influenza bacillus fell into groups like the pneumococcus IV, by subdivision of strains. As many as fifty colonies were taken from a single individual and the same strain was found. Animal passage did not change it. Thus it would seem that this was not the true cause of the epidemic, because if it were, patients would be infected by the one strain. It would seem, therefore, that one knew nothing of the real cause of the epidemic, which opinion was held by most investigators. The organisms were probably the same as in measles and other exanthemata. It would seem that the passage of an unkown virus caused the mucus membrane to become vulnerable to the secondary invader. This unknown influence was an organism raised in virulence by passing from one to the other, and the influenza bacillus could be added to the list of secondary invaders.

The Pathology of Influenza.—Dr. WILLIAM G. MACCALLUM of Baltimore presented this paper. He said that while he would give his own impressions, he did not feel that the cause of the disease had been found. He would speak of the Pfeiffer bacillus, rather than the "influenza" bacillus, because it had not been shown that an influenza bacillus was concerned. All known organisms were secondary invaders; pneumococci were extremely prevalent. Ordinarily present in the throat, these organisms were able to produce pneumonia upon lowering of resistance. This was also true of the Pfeiffer bacilli, and the pneumonias did not differ greatly from one another. In the epidemic of pneumonia following measles at San Antonio in February, 1918, the hemolytic streptococcus was found. The influenzal pneumonia differed from this. Streptococcic pneumonia was of three types: In the first type the disease caused death in one or two weeks; in this form the bronchi were surrounded with nodules. If the patient survived longer (the second type), these nodules became confluent and made up walls of connective tissue against the invading streptococci. In the third type of cases there was streptococcic invasion of the whole lung with destruction of tissue. These types depended upon the amount of resistance. The autumnal cases were of different type: there was no accumulation of fluid in the pleural cavity. Examination showed patches on the surface of the lung, which were spongy, red, and watery, like extremely fresh consolidation areas. The Pfeiffer bacillus was associated with the formation of nodules in the bronchi. Many cases of pneumonia showed pure infection of different types and it would seem that there might be a regional distribution of the Pfeiffer bacillus, just as there was of streptococci. On the whole it was difficult to draw sharp distinctions as to the forms of pneumonia, though sometimes the bacillus of Pfeiffer, the streptococcus and the pneumococcus were distinctly separated.

Dr. AUGUSTUS WADSWORTH of Albany, N. Y., said that they had studied bacteria from cases involved and also lesions produced experimentally in the lung. The practical value of vaccines prepared from the influenza bacillus had been tried out in state institutions, as these places offered the best opportunity for a careful and accurate estimation of the value of preventive inoculation. One could not but be struck with the uncertainty of all results and the necessity of care in drawing conclusions. The essential conditions should be borne in mind under which the etiological rôle of the organism of the infectious process is established, namely, the organism at some stage must be isolated in pure culture and must give rise to a characteristic lesion in animals, and then again be isolated in pure culture.

None of these conditions had been fulfilled in influenza, so that one had not passed beyond the stage of recording observations. In animal experimentation the invariable presence of a filterable organism had not yet been established and one could not be certain that the lesions incited experimentally were those of influenza. This point had been emphasized by English and French workers, that similar lesions could be obtained by different bacteria. Early study with the influenza bacillus failed to reveal it but later its presence was established in nearly all the districts of the state in which it was looked for. The cultural differences of the influenza bacillus were apparently similar but probably the standardization of reactions was inadequate. The thermal limits of growth had been found to vary depending upon the favorable character of the medium from 40° to 41° C. Nearly all failed to grow above 40.5° C. Not sufficient attention had been paid to this fact. In regard to carbohydrates, 40 strains were found to acidify glucose and ten formed gas. The meaning of this was not clear and care was necessary in drawing conclusions. The toxicity of cultures varied greatly. Very seldom infection developed and most animals were killed by the toxic action. Filtrates of the cultures were toxic. Cultures injected into the trachea were similar to human lesions and showed a hemorrhagic pneumonitis. Influenza did not develop in the animals, however. In 24 hours pure cultures could be isolated, but in 48 hours no cultures were obtained. The animals were relatively insusceptible to the agent. Vaccine therapy was based upon the assumption that the disease was due to a specific agent—possibly the influenza bacillus. Studies were made in 28 institutions with a total of 39,263 inmates. 5,113 persons received 3 doses of vaccine. There were many more cases in the vaccinated than the nonvaccinated. In one institution the standard dosage was doubled and there the proportion of cases in the vaccinated and unvaccinated was the same. In other institutions there were less in the vaccinated than in the unvaccinated. In one institution quarantined, 450 inmates were vaccinated. No influenza developed for 3 months, then there were over 200 cases; 166 in the vaccinated and 37 in the nonvaccinated. 38 persons had the influenza bacillus in the discharge.

Dr. A. W. Williams of New York said that there was no necessity for wasting any time in determining whether the organism was pathological or not. One must pay attention to postulates and prove whether there was one strain responsible for the epidemic, and the test to prove this must be determined. Up to the present time it had been decided that, until it proved worthless, the agglutination of strains with the absorption of agglutinins should be the ultimate test. The strains of the influenza bacillus had been shown not to respond to the test. Each case was a law unto itself. If therefore the agglutination test could be accepted as valid, the influenza bacillus had nothing to do with the epidemic.

Dr. E. L. Le Count of Boston said there were certain salient points to be noted in connection with this disease, and one of the most essential was the way in which it spread. It had been compared to measles and similar eruptive fevers. If the human race were as susceptible and not immunized, measles would spread in a similar manner. Outside of such a conception, there was nothing with which to compare influenza. The cause would seem to be unique, although the clinical manifestations were fairly clear. From the pathological work one was getting something of an entity out of the changes that occurred in the body, and there were certain features of the lung lesion that were conspicuous. There was an exceeding wetness of the lungs and the fluids of the body ran into the pleural cavity. Perhaps it was a mistake to withdraw these fluids from the pleural cavity. Microscopically few features were conspicuous. There was a thin layer of fibrin which might cause necrosis of the air passages. This fibrin layer with subsequent necrosis was unique in lung inflammations. The speaker said he had reported cases of minute necrosis in the capillary cells, but he did not know how much this was found in influenza. The capillary necroses were probably primary. Another point was that 15 years ago in New York and Chicago they called lobar pneumonia "lung fever". They became familiar with the post mortem picture. Since the epidemic they had not seen much of the old type of lobar pneumonia or the disease with leucocytosis, chill, and fever. The new kind was not clinically or anatomically the same as that of 15 years ago.

Dr. Albert of Iowa City said that he thought that there was some evidence of immunity to influenza. In a state institution of 162 persons there were 5 different cottages. Early in October the disease got a foot-hold. The officials isolated the inmates of two cottages. 80 persons contracted the disease and as the result of careful isolation it did not spread. 2 months later every person was exposed. During the second epidemic 76 persons took it, and there was not a single reeurrence of the disease among the first set who took it. Twelve persons did not contract the disease during the two epidemics. There must have been some development of immunity.

Dr. Selby of Toledo, O., said that these papers were by authorities and leaders and the meeting had been impressed with the need of further research. He would suggest a resolution that the Congress of the United States be urged to appropriate one million five hundred thousand dollars for investigation of the causes, treatment and cure of influenza, this sum to be available by July 1, 1922.

Dr. Tomlinson of Arlington, Del., said that it was admitted that the organism had not yet been discovered, so that the profession were most interested in continuing research so that it might be discovered. Vaccines could not be of service until they were made from the organism that produced the disease. At the meeting of the American Public Health Association in Chicago Dr. Vaughan made the statement that we did not know more about pneumonia than we did one hundred years ago. The discussion on influenza waged for three days from every point and angle. The result was expressed in the lines:

> "It windeth in and windeth out,
> And still it leaves the mind in doubt,
> Whether the snake that made the track
> Was going North or coming back."

Dr. Alexander Lambert of New York said that the resolution should be turned over to the Board of Trustees, ad interim. Resolutions made by the sections were acted upon by a committee of the Board of Trustees. Dr. Lambert added that he was interested in the pneumonias before and after 1889. In 1885-8 the pneumonia was called lobar pneumonia. In 1889, in New York, they began to see unusually boggy lungs with maximum transudate and minimum exudate. These were believed to be pneumonias and the streptococci were isolated. For four or five years the pneumonias were bronchopneumonias; they then began to return to the purely lobar type. In 1901 with the grippe the bronchopneumonias were seen. They returned to the lobar type and now again were coming back to the broncho type. Differentiation of primary and secondary infections should be made. The interpretation of the *x*-ray plates was of assistance. Thirty-five years ago Dr. Delafield did a lot of work on this subject, and this generation was now taking up the problem with better opportunities for solving it.

Dr. H. B. Wood of Providence, R. I., said that a house-to-house canvass in New York State showed that 20 per cent. of persons clearly exposed contracted the disease. It had the same infectiousness as measles. There was no influence of sex on the duration and number of cases.

The Symptoms and Complications of Influenza.—Dr. Lewis A. Conner of New York City presented this paper. In 1918 the speaker said the influenza in the army camps was of mild type with no serious complications. The clinical picture was clear cut. There was usually a three days' incubation period, but sometimes only forty-eight hours. Fever, headache, backache, pains, cough, mental dullness were symptomatic; weakness persisted after the symptoms had disappeared. The cough was dry, and a husky voice was due to the dryness of the pharynx. Epistaxis was present in one-fourth of the cases. The respiratory rate was low in relation to the height of the temperature. A rise of respiratory rate was significant of pneumonia. Leucopenia was present in the blood picture. Nervous symptoms were headache, apathy, somnolence, depression of

spirits. Sometimes there was nausea with vomiting. A flushed face with injected conjuctivæ was noted, and suggested measles. Sometimes there was an erythematous rash. A surprising immunity of the urinary tract was noted. The time necessary for recovery varied greatly from a few days to many weeks. In one type of fulminant cases there were extreme cyanosis, air hunger, and intense congestion without actual pneumonia. These patients died in twenty-four hours. A subcutaneous embolism was noted in a few cases, due to rupture of the air vesicles.

Further Studies on Prophylactic Inoculation in Influenza and Pneumonia.—Dr. EDWARD C. ROSENOW of Rochester, Minn., read this paper. In the study of the use of vaccines in persons who contracted serious symptoms of the disease it was necessary that the killed bacteria must be of the kind that were contributory to the cause of death. The primary cause was unknown, but it was known what caused death, and these organisms could be found in the lesions. The bacteria concerned were therefore incorporated in the vaccines. Prophylactic vaccination had been carried out on a large scale by Wright, Cecil, and Austin against pneumonia. Two million doses of mixed vaccine were sent out to physicians on the condition that reports be furnished as to results. The vaccines contained 30 per cent. typed pneumococci, and 40 per cent. type IV, 20 per cent. hemolytic streptococci, and 10 per cent. staphylococci. These were from cases of influenza. One hundred and seventy-four strains of green-producing streptococci were incorporated from time to time with the vaccine. This vaccine called forth antibodies. An increase of agglutinins was noted after injection, which persisted six weeks. Antibodies were formed against green-producing hemolytic streptococci and staphylococci. A comparison of the vaccinated and nonvaccinated was made; 934,476 persons were vaccinated once; 345,133 were not vaccinated. The nonvaccinated showed a pneumonia rate of 21 per thousand; the vaccinated 4.4 per thousand. The mortality rate of the nonvaccinated was 8 per thousand and that of the vaccinated 6.35 per thousand, counting from the date of the first injection. The pneumonia rate was 0.5 in the vaccinated and 5.5 in the nonvaccinated cases. In pregnant women the rate was 12 of the former as compared to 20 of the latter. Hospital mortality was 5 per cent. as compared to 22 per cent. Thus it was seen possible to lower definitely the incidence and mortality rate of influenza.

Present Status of Prophylactic Vaccination Against Influenza.—Dr. GEORGE W. MCCOY of Washington, D. C., in this paper, said that there never had been convincing evidence of the relation of the Pfeiffer bacillus to the disease. British and French workers claimed to have produced the disease by a filterable virus. The pneumonia was due to secondary invaders, and it was claimed by some that the influenza acted in producing the pneumonia, which might be true, as the latter disease presented a new type, and could be differentiated as differing from the lung lesion of lobar pneumonia. Prophylaxis of lobar pneumonia might be of no use in influenza. The organism might be a saprophytic one living in the damaged tissues, not even a secondary invader. In considering the question of vaccines it was said that a percentage of the total number of cases would have occurred before commencing vaccination, leaving a group of persons to be vaccinated who were not susceptible to the disease. This was hardly a fair comparison, as in institutions where half the inmates were vaccinated and half not, there was no difference between the two groups. At Pelham Bay Naval Station this equality was noted. At the Puget Sound naval base an increase of cases was noted among the vaccinated, but decrease of mortality. Results of vaccine were apparently encouraging, but the conditions were not trustworthy. Vaccines against pneumonic complications had been used. The experience of the English workers had showed that there might be danger in the indiscriminate use of vaccines in which persons in the negative phase of the disease might be attacked. There appeared to be increased susceptibility immediately after vaccination. It was found, moreover, that a vaccine had to be prepared to meet the needs of a particular locality. Thus, vaccine prepared in Chicago was of no use in California. The experience of Cecil and Vaughan at Camp Wheeler showed that influenza markedly lowered the resistance to pneumonia even in vaccinated men. The evidence as to prophylactic value of pneumococcus vaccine was not striking. In these circumstances Dr. McCoy said that a conservative attitude was justified. The vaccine seemed to have an influence on morbidity and mortality under properly controlled conditions.

Value of Convalescent Blood and Serums in the Treatment of Influenzal Pneumonia.—Dr. HENRY F. STOLL of Hartford, Conn., made this communication. He said that the transfusion of blood or serum of convalescents seemed not to be very definite in action. The serum of convalescents from influenza appeared to be of more value than normal serum. With the use of pneumonia convalescent serum an early improvement was noted in influenza patients with relief of symptoms—headache, cyanosis, nausea and vomiting, jaundice, followed by detoxication. No change was noted in the mental picture until forty-eight hours. Usually after improvement of symptoms the pneumonic process was not extended, although occasionally the *x*-ray showed extension after clinical improvement. A reaction was noted in 16 per cent. of the cases; 140 intravenous injections were made. A chill was sometimes of good omen, but a severe reaction in very sick patients might save life or might hasten death. Eighty per cent. of those that showed improvement had no reaction. The leucocytes rose from 3 to 23,000 after transfusion with convalescent serum. No difference was observed between results with citrated blood, plasma, and whole blood. Severe cases were treated, because there was a shortage of serum. Cases were classified as: (*a*) Mild cases; (*b*) prognosis rather against the patient; (*c*) prognosis seriously against the patient; (*d*) hopeless cases. It was found that if the cases received treatment early they showed more improvement; 83 per cent. of these improved. One patient, an officer's wife, was brought in moribund, and improved after receiving 100 c.c. convalescent serum. Another case was that of an officer of the French army with an extensive lesion of both lungs. He had seven injections and recovered. Another case of two-day-old pneumonia had only a small part of the right upper lobe normal. This patient had a chill after the third injection of 350 c.c. After that he was much better. Convalescent serum was used in a case of hemolytic streptococcus sore throat and the man was much improved.

The Treatment of Influenza by Means Other Than Vaccine and Serums.—Dr. JAMES B. HERRICK of Chicago presented this paper, which was based on the experiences of 1889-90, as well as the present epidemic; the experiences of other authors in personal communications and personal experience. The literature had been carefully studied and digested. Many studies were found to be superficial and to ignore the self-limitation of the infection and its natural course. It was well to ask, "Where does the profession stand in relation to drug treatment?" There was no specific treatment of the disease and no standard prophylactic or curative therapy. Quinine, warmly advocated by Italian physicians, was found without value. Segregation must be advised to lessen contact exposures, the susceptible being, as in measles, about 30 per cent. of the population. A diluent action could be gained by closing public gatherings, the cases would be milder and more scattered. Proper wearing of gauze masks by the patient protected nurses and attendants, but soiled masks probably did harm. The failure to transfer influenza by contact experiment acted to shake faith in the wearing of masks. The utter lack of uniformity of opinion as to treatment went to prove that there was no one remedy of choice. Points upon which all agreed were: Early and prolonged rest in bed; sunlight; fresh air; right diet with plenty of liquid; free movement of the bowels. One of the hardest things to do was to refrain from prescribing drugs because the diagnosis had been made. A large proportion of the patients did not need a single dose of medicine, treatment was expectant, and symptomatic. In a hospital ward in Chicago rest in bed before and after symptoms was the only treatment. The mortality was 0.6 per cent. One had the satisfaction of knowing that no lives were lost by drugs. Digitalis was given by intravenous injection when need arose. One-sixth of a grain of morphine was given when necessary. Hypo-

dermoclysis was sometimes helpful. One need not be a nihilist in drugs, but there was a danger in overdrugging which was real and not imaginary.

Dr. FRANK W. HARTMEN of the U. S. Navy said he could confirm Dr. Herrick's reports. At the naval academy they had 1500 men and as soon as any of them developed temperature or signs in the lungs they were put to bed and kept there. There was low incidence of pneumonia and only 4 deaths. The work of Dr. Stoll should put the treatment with convalescent serum on a better basis. The results with the serum of vaccinated persons did not seem very definite. One could not yet draw conclusions. One French worker claimed that the results were non-specific. The reactions were severe and should be avoided if possible, especially in children and in old or weak persons. This could be avoided by intramuscular injection, when the recovery would be slower, but as good. Serum from a number of convalescents could be pooled. The reports of ten observers on this work were favorable.

Dr. S. SOLIS COHEN of Philadelphia said that he agreed with Dr. Herrick's philosophy, but not with his application of it. To say that the fact that there were a number of drugs advised proved all were worthless, was not logical; some of them might be helpful. As a clinician entitled to have an opinion, he would say that there was no general agreement on the method of treatment, but there was unfortunately an agreement on the use of two very harmful drugs which shot up the mortality peak in Philadelphia: these were aspirin and phenacetin. Nearly every day he saw cases in which the treatment was Dover's powder and aspirin; that often spelt death. Sodium salicylate was helpful, although not a specific. Quinine was helpful in some cases of pneumonia. Da Costa had said that influenza was the least fatal and most fatal of all diseases. If one thing had been brought out it was that the term mixed infection was not sufficient. The virus was not known and it was certainly not the Pfeiffer bacillus. It must be studied from the standpoint of a bacteriological and malignant symbiosis. The effect of the influenza virus, plus whatever other pathological and bacteriological factor might be present, was the extreme depression of the vasomotor, respiratory, and vital forces. The temperature was often subnormal. The use of morphine under the proper indications together with hygienic aids would procure better results.

Dr. H. L. GOLDSTEIN of Camden, N. J., said that he had heard many expert opinions. Dr. Herrick was fortunate to be able to treat 150 cases with hospital rest, from the very beginning, but what was the general practitioner to do? This was the Victory meeting of the greatest medical association on earth, and what was the sum and substance that one was to carry away? "We don't know the cause of influenza." The question rose then, "Was one justified in using combined vaccines?" He thought one was, even if one did not know the cause of influenza. At one time they didn't know the cause of syphilis, but that was no reason for rejecting mercury. They did not know the cause of rheumatism, but that was no reason for not using salicylates. Even if the cause were found, that would not mean that a cure-all was found. The mass of the people would not be treated by experts in hospitals but by the general practitioner. The Association should delineate a definite method of treatment, and no doubt combined vaccines could be used under the proper dosage and conditions. The profession owed it to the public to use such means as they had at hand.

Dr. F. T. LORD of Boston said that there was no theoretical ground for believing that vaccine would be of any value; it might be of use in prophylaxis, but its value in treatment was not proven. In regard to serums, Neufeld, Henderson, Dochez, and others had proved that there was a protective substance in the blood after the pneumonia crisis, but it was not constantly present, so that sometimes results would be lacking. The only way to judge was by simultaneously controlled cases. At the Massachusetts General Hospital, of 23 patients treated with serum 6 died; of 25 treated without, 3 died.

Dr. A. E. FUSSELL of Philadelphia said that in 1889 there were the same disease and the same organisms. Uncomplicated influenza cured itself. The complicated kind was different. The present epidemic was increased by crowding of troops and by the underfeeding and anxiety of the civil population. One symptom noted sometimes was jaundice and tenderness of the gall-bladder; perhaps there was catarrhal cholecystitis. In regard to drugs, digitalis was the sheet anchor. Adrenalin was useful with proper indication. Bicarbonate of soda was helpful. Eight per cent. of pneumonias showed kidney involvement.

Dr. W. WALKER of Chicago said that *B. septicus* was found in 55 per cent. of cases of acute rhinitis. It was sometimes called *B. segmentosus*. It belonged to the diphtheroid group. The fundamental principle of Wright in regard to vaccine was the giving of very small doses. Dr. McCoy apparently gave enormous doses. This increased the susceptibility of the patient.

Dr. M. K. WYLDER of Albuquerque, N. M., said that he had insisted on a close quarantine in a girl's college, and no cases occurred. One mother, however, insisted on taking her daughter out, and the girl took the disease and died. There was no trouble in keeping quarantine after that. He did not know who was to be the Moses who was to lead them to the promised land, but he hoped that in 1920 the meeting would publish a preventive for influenza.

Dr. W. C. WOODWARD said that referenee had been made to closing public buildings. He felt that in respiratory epidemics discharges from the respiratory tract were as dangerous as those from the urinary or digestive tracts, and the public should exercise as much care in regard to coughing, sneezing, and the care of eating and drinking utensils as was considered necessary in regard to the discharge and disposal of urinary and fecal matter.

Dr. C. C. BROWNING of Los Angeles, Cal., said that they had found that men from mountainous districts, unaccustomed to overcrowding, suffered very severely from influenza. Some died 24 or 48 hours after arrival at camp. These men were not undernourished.

Dr. H. H. KOONS of Washington, D. C., said that he favored the use of vaccines. At Camp Houston he used vaccine very carefully at first and got uniformly good results. Within 36 hours he got decline of temperature and pulse rate, lessening of cyanosis and marked general amelioration. The treatment consisted of rest in bed, fresh air and liquid diet. The pneumonia mortality rate in the wards where vaccine was used, was under 7 per cent. In the other wards it was 18 per cent. Vaccine was used intravenously and 100 cases were treated.

Dr. W. A. BASTEDO of New York City said that there was no evidence that more aspirin and phenacetin were used in Philadelphia than in other towns. Most patients seen had had these drugs administered.

Dr. E. C. ROSENOW said that the vaccines he used were made as correctly as it was possible to make them. Patients were immunized to the organisms that caused death, and this had nothing to do with the virus which initiated the original attack. To make the mortality incidence less was a perfectly logical conclusion. The immunity seemed to be short-about 6 weeks or two months.

Dr. HERRICK said that the general practitioner should get hold of the patient as early as possible and insist on his going to bed and staying there. He personally had not used vaccines or serum because he had not felt it was proved that they were helpful. They might even be harmful. As Osler said, "Experience is fallacious; judgment difficult."

Deaths While Eating.—Martin describes two sudden deaths while eating in healthy individuals. In one a large piece of meat wedged in the esophagus obstructed the glottis and strangled the patient. The second case was an exact duplicate of the first, even in the size and shape of the foreign body. It is remarkable that there were no premonitory symptoms to aid in the diagnosis. Autopsy was necessary in each case to determine the cause of death, for the doctors hastily summoned were unable to determine the nature of the condition and hence could have administered no rational treatment.—*La Presse Médicale.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NATIONAL BOARD OF MEDICAL EXAMINERS.

Chicago and New York, December 2-19, 1918.

ANATOMY.

1. Describe the circulation in bone and discuss the growth and repair of bone tissue.
2. Give the relations, divisions, and branches of the subclavian and axillary arteries.
3. Describe the liver.
4. Give the attachments, action, and nerve supply of the following muscles: (*a*) brachialis anticus; (*b*) orbicularis palpebrarum; (*c*) biceps femoris; (*d*) psoas magnus.
5. Discuss the surgical anatomy of the shoulder joint, especially with reference to compound fractures and dislocations such as arise from gunshot injuries.

PHYSICS AND CHEMISTRY.

To answer the first four questions in physics is optional:

1. (*a*) What is a solution? What is an emulsion? Give examples. (*b*) What is osmosis? Give illustrations of osmotic pressure. (*c*) What is meant by specific gravity? (*d*) Give the methods of determining the specific gravity of solids, fluids, and gases.
2. (*a*) What is meant by refraction of light? (*b*) Draw biconvex and biconcave lenses and illustrate their effects on rays of light. (*c*) Draw the lenses of a compound microscope and illustrate the function of each lens.
3. (*a*) What is the spectroscope? What use has it in medicine? (*b*) What is the ophthalmoscope and its use? (c) What is the laryngoscope and its use?
4. (*a*) What is sound? (*b*) Define the terms pitch, intensity, and quality as applied to sound.
5. (*a*) What is meant by an ion and an ionization? (*b*) What is an electrolytic dissociation? Give an illustration.
6. (*a*) What is the chemical composition of calomel, Glauber's salts, Rochelle salts, alum, and Dover's powder? (*b*) Define an acid, a base, and a salt. (*c*) What is an alkaloid? (*d*) Give three alkaloids used in medicine.
7. (*a*) Define and classify carbohydrates. (*b*) Mention the most important carbohydrate foods, and trace a bit of starch through the body. (*c*) Give the most important effects of abnormal carbohydrate metabolism.
8. (*a*) What is a fat, a fatty acid, a soap? (*b*) Trace a bit of fat through the body. (*c*) What are the results of abnormal metabolism?
9. (*a*) What is a protein? (*b*) What are the approximate constituents of proteins? (*c*) Trace a bit of egg white through the body. (*d*) Discuss some of the more important phenomena of abnormal protein metabolism.
10. (*a*) Give the composition of the blood. (*b*) What changes occur in the blood in structural diseases of the liver and kidney, and in diabetes?

ANSWERS.

ANATOMY.

1. The *vascular supply of bone* is derived from (1) the periosteum; in addition, the long bones are supplied by (2) the nutrient arteries, which pass into the interior of the bone and then divide into ascending and descending branches, and anastomose with the vessels from the periosteum, and (3) the articular arteries which supply the articular ends. The veins, in many bones (vertebræ, diploe, etc.), often run in canals, have thin walls, do not collapse when cut across, and may be dilated.

"The *growth* of bone manifests itself in three different directions: (i.) It increases in length from the shaft side of the epiphyseal cartilage, the epiphysis itself growing but little. In the upper limb the chief increase in length occurs at the shoulder and wrist, whilst in the leg it is mainly evident on either side of the knee-joint, and this in spite of the fact that the so-called nutrient arteries are directed away from these points. (ii.) Increase in breadth is produced by new formation under the periosteum. There is some difference of opinion as to whether this membrane has any true bone-forming power. That bone is formed from it when stripped up is undoubted; but it is possible that the angular nucleated osteoblasts found on its under surface have been derived from the bone itself by the process of detachment, which necessarily tears through or drags out the vessels which pass from the periosteum into the bone. (iii.) A bone increases in density by a new deposit of osseous tissue around the Haversian canals and cancellous spaces."—(*Rose and Carless' Surgery.*)

Repair of Bone: "The broken ends of the bone are rough and irregular, and the periosteum is torn more or less, but some portion usually remains as a bridge between the fragments. The soft structures in the neighborhood are lacerated, so that the parts are infiltrated with blood-clot, which fills up the spaces between the bone ends. As in repair of any other part, the blood-clot in a few hours is infiltrated with leucocytes, whose duty it is to absorb the clot. The connective-tissue cells in the surrounding parts proliferate, and the bone undergoes rarefying osteitis, so that the place of the blood-clot is taken by granulation tissue. The granulation tissue becomes calcified, and the calcified tissues ultimately replaced by bone. The periosteum plays a large part in the ossification of the new tissue. It becomes stripped up for some distance, hyperemic, and thickened. Granulation tissue is formed from it, and unites with that which has replaced the blood-clot. This mass binds the bone together and forms the *provisional* or *ensheathing callus*, which is subsequently ossified by the growth of the periosteal osteoblasts spreading over the mass. The medulla becomes plugged with granulation tissue or *internal callus*, and this, as well as the granulation tissue lying between the fragments of compact bone, becomes ossified, the bone cells of the compact tissue probably proliferating to take part in the repair." (*Aids to Surgery.*)

2. *The subclavian artery* is divided into three parts by the scalenus anticus; the first part being from the origin of the artery to the inner border of the scalenus anticus; the second part, posterior to that muscle; and the third part from the outer edge of the muscle to the lower border of the first rib.

Relations of first part of right subclavian. In front: Skin, fascia, platysma myoides, sternomastoid, sternohyoid, sternothyroid; internal jugular, vertebral, and anterior jugular veins; vagus, sympathetic and phrenic nerves. *Behind:* Longus colli, and sympathetic, vagus, and recurrent laryngeal nerves. *Below:* Pleura and recurrent laryngeal nerve. *Below:* Pleura and recurrent laryngeal nerve.

Relations of first part of left subclavian. In front: Left pleura and lung; left internal jugular and innominate veins; sternomastoid, sternohyoid and sternothyroid; vagus, sympathetic and phrenic nerves. *Behind:* Esophagus; thoracic duct; sympathetic and vagus nerves; longus colli. *Externally:* Pleura and lung. *Internally:* Esophagus, trachea and thoracic duct.

Relations of second part of right and left subclavians. In front: Skin, fascia, sternomastoid, scalenus anticus; transversalis colli and suprascapular arteries; phrenic nerve. *Behind:* Pleura; scalenus medius; first dorsal nerve. *Above:* Brachial plexus. *Below:* Pleura.

Relations of third part of right and left subclavians. In front: Skin, fascia, platysma; plexus of veins from anterior and external jugulars; cervical plexus; clavicle; subclavius; suprascapular artery. *Behind:* Scalenus medius. *Above:* Posterior belly of omotyoid; cords forming brachial plexus. *Below:* First rib.

Branches of subclavian artery: Vertebral, thyroid axis (giving off inferior thyroid, transversalis colli and suprascapular), internal mammary, and superior intercostal arteries.

Relations of Axillary Artery. In front: Skin; fascia; pectoralis major and minor; costo-coracoid membrane; external anterior thoracic, inner head of median and internal cutaneous nerves; cephalic and acromiothoracic veins. *Behind:* First intercostal serratus magnus, subscapularis, and tendons of latissimus dorsi and teres major muscles; posterior thoracic, internal anterior thoracic, musculospiral, and circumflex nerves,

also posterior cord of brachial plexus. *Outer side:* Coracobrachialis; brachial plexus, and median and musculocutaneous nerves. *Inner side:* Axillary vein; ulnar, lesser internal cutaneous, and internal anterior thoracic nerves, and inner cord of brachial plexus.

The *axillary artery is divided* into three parts by the pectoralis minor muscle. The first part lies above this muscle, the second part beneath it, and the third part below it.

The *branches of the axillary artery* are: Superior thoracic, acromiothoracic, long thoracic, alar thoracic, subscapular, anterior and posterior circumflex arteries.

3. "The *liver* is the largest gland in the body, measurin its transverse diameter from ten to twelve inches, and its anteroposterior six to seven, and its thickest part about three inches, and weighing about three to four pounds. It occupies the upper part of the abdominal cavity, and the right hypochondriac, epigastric, and a portion of the left hypochondriac regions. Its upper surface is convex and rests against the diaphragm and a small portion of the abdominal parietes in front. Its lower surface is in contact with the duodenum and stomach, the right kidney and suprarenal capsule, and the hepatic flexure of the colon. It is divided by the longitudinal fissure into the right and left lobes. The liver has five fissures, five lobes, five ligaments, five sets of vessels, and is inclosed in a fibrous coat, continuous at the transverse fissure with the capsule of Glisson. It is also invested by the peritoneum, except at the attachment of the coronary ligament." (Young's *Anatomy.*)

The *fissures* are: Umbilical, of ductus venosus, of gall bladder, transverse, and for inferior vena cava.

The *lobes* are: Right, left, caudate, quadrate, and spigelian.

The *ligaments* are: Falciform, 2 lateral, coronary, round and of ductus venosus.

The *vessels* are: Hepatic artery and veins, portal vein, and hepatic duct.

4. BRACHIALIS ANTICUS. *Origin:* The lower half of the anterior surface of the humerus, and the front of the external and internal intermuscular septa. *Insertion:* The inner part of the rough spot on and below the coronoid process of the ulna. *Action:* Flexor of the forearm. *Nerve supply:* Musculocutaneous, and a twig from the musculospiral.

ORBICULARIS PALPEBRARUM *Origin of orbital portion:* Internal tarsal ligament, internal angular process of frontal bone, and nasal process of superior maxilla. *Origin of palpebral portion:* Internal tarsal ligament. *Insertion of orbital portion:* Same as the origin. *Insertion of palpebral portion:* External tarsal ligament. *Action of orbital portion:* Depressor of eyebrow, and elevator of the skin of infraorbital region. *Action of palpebral portion:* It closes the eyelids and aids in the removal of tears. *Nerve supply:* Facial nerve.

BICEPS FEMORIS. *Origin:* Tuberosity of ischium, outer lip of linea aspera and upper part of external supracondylar ridge of femur and external intermuscular septum. *Insertion:* Upper part of head of fibula in front of the styloid process, and external tuberosity of tibia. *Action:* Extensor of hip joint, flexor of leg on thigh, and external rotator of leg. *Nerve supply:* Great sciatic.

PSOAS MAGNUS. *Origin:* Front of transverse processes of lumbar vertebræ, sides of the intervertebral substance between lumbar vertebræ. *Insertion:* Lesser trochanter of femur. *Action:* Flexor of thigh on pelvis or pelvis on thigh; the muscle of one side acting alone may cause lateral flexion of the lumbar part of the spinal column. *Nerve supply:* From lumbar plexus, chiefly second and third lumbar nerves.

5. The *shoulder joint* is an enarthroidal joint formed above by the glenoid cavity of the scapula and below by the head of the humerus. Its ligaments are glenoid, coraco-humeral, and capsular. The glenoid surrounds the edge, deepens the glenoid cavity, and is continuous above with the long head of the biceps tendon. The capsular ligament, extensive and loose, arises above it from circumference of glenoid cavity behind the ligament, is attached below to the anatomical neck of humerus, and is pierced by tendons of two or three muscles. The coraco-humeral, or accessory, is a fibrous band which extends obliquely downward and outward from the coracoid process to the anterior part of great tuberosity, strengthening the capsular ligament. A *synovial membrane* lines the joint, and forms the bursa under the subscapularis. It is reflected round the tendon of the biceps, and lines the bicipital groove. The *nerve supply* is from the circumflex and suprascapular nerves. The arteries are branches of the anterior and posterior circumflex, and the suprascapular.

The *muscles in relation with the joint* are: above, the supraspinatus; below, the long head of the triceps; in front, the subscapularis; behind, the infraspinatus and teres minor; internally, the long head of the biceps. The deltoid covers the joint in front, behind, and externally.

The shoulder joint relies for its strength mainly on its muscles. The capsule is very lax, and the glenoid cavity is very shallow.

Injuries may involve the soft parts only, and these are more difficult to deal with; or there may be fissures into the joint leading from fractures of the epiphyseal end of the bone; or there may be extensive articular injuries; or joint injury with involvement of muscles, vessels and nerves.

PHYSICS AND CHEMISTRY.

1. A *solution* is a homogeneous liquid containing a certain amount of a gas, liquid, or solid dissolved in it. Salt or sugar in water will form a solution.

An *emulsion* is a watery fluid containing a liquid fat in a state of fine and permanent subdivision and suspension. Milk is an emulsion.

Osmosis is the passage of liquids and of substances in solution through a membrane or porous substance.

Examples of osmosis in the human economy: "In the body we have aqueous solutions of various substances separated from one another by membranes. Thus we have the endothelial walls of the capillaries separating the blood from the lymph; we have the epithelial walls of the kidney tubules separating the blood and lymph from the urine; we have similar epithelium in all secreting glands; and we have the wall of the alimentary canal separating the digested food from the blood vessels and lacteals."—(Halliburton's *Physiology.*)

Specific gravity of a substance is the weight of a given volume of that substance as compared with the weight of an equal volume of some other substance taken as a standard, under like conditions of temperature and pressure.

The *specific gravity of solids may be determined* by the use of:—(1) Hydrostatic balance, (2) Hydrometer, (3) Pyknometer.

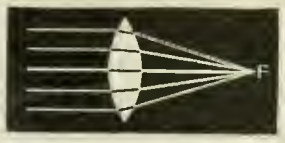
The *specific gravity of liquids may be determined* by the use of:—(1) Hydrometers, (2) Hydrostatic balance, (3) Specific gravity bulbs, (4) Specific gravity bottle.

The *specific gravity of gases may be determined* by the use of:—(1) Rate of diffusion, (2) by dividing the weight of the molecule by 2, (3) on the principle of the specific gravity bottle. In (1) and (2) hydrogen is taken as the standard, in (3) air is taken as the standard.

2. *Refraction of light* is the bending or deflection which a ray of light undergoes in passing obliquely from one medium to another. In passing from a rarer to a denser medium, the ray is bent toward the perpendicular; in passing from a denser to a rarer medium the ray is bent away from the perpendicular.

A *biconvex lens* causes parallel rays of light to converge; they are thus brought to a focus.

A *biconcave lens* causes parallel rays of light to diverge.



The action of a biconvex lens on parallel rays

The action of a biconcave lens on parallel rays

A *compound microscope* consists, essentially, of two convex lenses mounted on the same optical axis. One lens is small, but very powerful, and is called the *objective;* it forms an inverted, real and magnified image of the object which is placed near it, but beyond

its focal distance. This magnified image is viewed through the *eye-piece*, which acts as a magnifying glass, and produces a still more enlarged image.

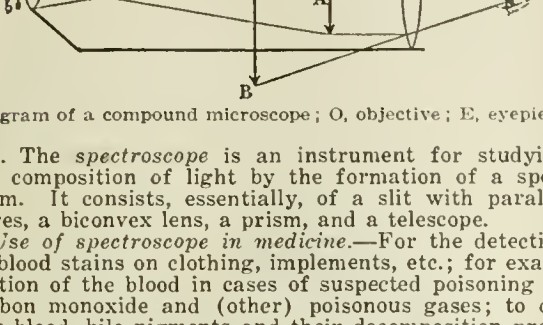


Diagram of a compound microscope; O, objective; E, eyepiece.

3. The *spectroscope* is an instrument for studying the composition of light by the formation of a spectrum. It consists, essentially, of a slit with parallel edges, a biconvex lens, a prism, and a telescope.

Use of spectroscope in medicine.—For the detection of blood stains on clothing, implements, etc.; for examination of the blood in cases of suspected poisoning by carbon monoxide and (other) poisonous gases; to detect blood, bile pigments and their decomposition products in urine, and pathological fluids.

The *ophthalmoscope* is an instrument for examining the interior of the eye by light.

It is used to examine the fundus of the eye, the sclerotic, choroid, retina, optic nerve, vessels of the retina; for the detection of optic neuritis, retinitis, and hemorrhages, embolism of the central artery of the retina. It is an aid to diagnosis in various injuries of the head, and spinal cord, in nephritis, diabetes, pernicious anemia, syphilis, tuberculosis, alcoholism, lead poisoning, and other diseases.

The *laryngoscope* is an instrument for examining the interior of the larynx; it is, essentially, a combination of two mirrors by which a view of the larynx is obtained. The vocal cords, epiglottis, cartilages, base of the tongue, and lower parts of the pharynx may be inspected by its use; changes in the color, form, mobility, and functional activity of these parts may be observed.

4. *Sound* is the effect produced on the auditory nerve by the vibrations of a sonorous body.

The *pitch of a sound* depends on the number of vibrations; the greater the number of vibrations in a second, the higher is the note.

The *intensity of a sound* depends on the energy with which it is propagated; it is generally called *loudness*.

The *quality of a sound* depends on the form of the sound wave or the number and strength of its overtones. The same musical note sounded on a piano and on a cornet differs in *quality*.

5. *Ions* are the primary products of electrolysis; those which separate at the anode are called *anions;* those which separate at the cathode are called *cations*.

Ionization is the process of dissociation into ions which occurs when an electrolyte is dissolved.

Electrolytic dissociation is the decomposition of a molecule into ions which occurs when an electrolyte is dissolved. A solution of potassium chloride contains not only the molecule KCl, but also the cation K and the anion Cl, and the action of the current is to separate these, already liberated, ions at the respective electrodes. It is assumed that the hydrogen and metallic ions are charged with positive electricity, and the hydroxyl and acid-residue ions with negative electricity, and therefore the former are attracted to the negatively charged cathode and the latter to the positively charged anode.—(From Witthaus and Scott's *Text-book of Chemistry.*)

6. *Calomel* is mercurous chloride, HgCl. *Glauber's salt* is sodium sulphate, Na_2SO_4. *Rochelle salt* is sodium potassium tartrate, $NaKC_4H_4O_6$. *Alum* is a double sulphate of an alkaline metal and of aluminium or chromium or iron; potassium alum is potassium aluminium sulphate, $KAl(SO_4)_2$. *Dover's powder* is a powder containing 10 per cent. each of ipecac and opium, with sugar of milk.

An *acid* is a compound of an electronegative element or residue with hydrogen, part or all of which hydrogen it can part with in exchange for an electropositive element, without the formation of a base. *Example:* Nitric acid, HNO_3.

A *salt* is a compound formed by substituting a basylous element for the replaceable hydrogen of an acid. *Example:* Potassium nitrate, KNO_3.

A *base* is a ternary compound which is capable of entering into double decomposition with an acid, to form a salt and water. *Example:* Potassium hydroxide, KOH.

An *alkaloid* is an organic, basic substance, containing nitrogen, and capable of combining with acids to form salts in the same way that ammonia does; most of them are alkaline in reaction and bitter in taste.

Three alkaloids used in medicine: Morphine, strychnine, and atropine.

7. *Carbohydrates.*—The name carbohydrate was originally given to the group of compounds found chiefly in vegetables, and containing the elements of carbon hydrogen, and oxygen; the molecule contained six or some multiple of six times the atom of carbon, and hydrogen and oxygen in the proportion to form water. The name is not a good one, and the definition is not accurate; but the term is still used to denote a group of substances which includes the various starches, sugars, and gums, etc. They are generally divided into three groups: monosaccharides, disaccharides, and polysaccharides.

Important carbohydrate foods are: Sugar; sugar products, such as candy, jelly, marmalade, and preserves; potatoes; bananas; wheat and corn products; rice, sago, and tapioca.

Cooked starch is acted upon in the mouth by the ptyalin and maltase of the saliva; the former of these enzymes converts the starch into maltose, and the latter turns this into glucose. The intermediary stages are from starch to erythrodextrin, to achroodextrins, to isomaltose, to maltose. In the stomach the action of the ptyalin continues for a time, until the acidity of the gastric juice prevents its further action. In the small intestine, the amylopsin of the pancreatic juice hydrolyzes starch to maltose through the stages of dextrin and isomaltose. The maltose is converted into glucose, which is diffusible through the membrane lining the intestine, and is absorbed and passes into the circulation by way of the portal vein. Glucose is carried to the muscles, where some of it is converted into glycogen and stored (just as it is in the liver); as the needs of the body require it this glycogen is reconverted into glucose, which is oxidized in the body to carbon dioxide and water (with lactic acid, perhaps, as an intermediary substance). The bacteria in the intestine split the glucose into fatty acids, methane, and carbon dioxide.

The most important effects of abnormal carbohydrate metabolism are: Glycosuria, diabetes, and acidosis.

8. *Fats* are mixtures in varying proportions of the triglycerides of palmitic, stearic, and oleic acids.

Fatty acids are the acids of the acetic and acrylic series, the former being saturated and the latter unsaturated. A *soap* is a mixture of the stearate, palmitate, and oleate of sodium or potassium.

In the body fats are digested by the process of hydrolysis—the glycerol ester being split up into glycerol and the fatty acid. This process begins in the stomach, where the enzyme known as gastric lipase acts on emulsified fat. In the small intestine, the steapsin of the pancreatic juice hydrolyzes the fats into glycerol and fatty acid; this is the chief factor in the digestion of fats. The bile assists in the digestion of fats by the formation of soaps and emulsions. The fatty acids are not capable of being diffused through the cell membranes, but their alkali salts (or soaps) are capable of being thus diffused. The glycerol is absorbed directly. The products thus absorbed are taken up by the lymphatics and so conveyed to the blood. The hydrolyzed products of the fats are re-synthesized to fat in the wall of the intestine; and there is some doubt as to whether free unchanged fat is directly absorbed as such. In the blood(as well as in the lymph) the products of fat digestion appear as fat, and not as glycerol and fatty acids. In the blood and muscles the fat is oxidized; or if not required for energy, it is deposited in the body as fat and is drawn upon as required. There is a question as to whether fat is converted into glucoso in the body. Eventually fats are broken up into water and carbon dioxide.

Results of the abnormal metabolism of fat: Fatty infiltration, fatty degeneration, obesity, lipemia, fat necrosis, acetonuria.

9. *Proteins* are complex organic bodies which contain nitrogen. They are formed by living matter, and are found in the tissues and fluids of plants and animals. They contain carbon, hydrogen, oxygen nitrogen, and sulphur, and (sometimes) other elements.

They are composed of smaller molecules—amino-acids, which consist of two groups: (1) an amino group, and (2) an acid group with an acidity like that of acetic acid. Up to the present eighteen different amino-acids have been found in the constitution of proteins.

The egg white is acted upon in the stomach by the pepsin of the gastric juice which by hydrolysis splits it into proteoses and peptones, and some polypeptides and amino-acids. In the small intestine, the trypsin of the pancreatic juice acts similarly on the protein, and carries the process further, converting all protein into polypeptides and amino-acids. The enterokinase also acts upon the derived proteins, proteoses, peptones, and polypeptides converting them into amino-acids. These latter are soluble and diffusible, and are absorbed (possibly with some polypeptides) by the small intestine and carried to the portal vein. It is believed that during the absorption of these amino-acids and polypeptides through the wall of the intestine a re-synthesis of the protein occurs.

It is not accurately known by what steps the food protein is changed to blood protein and then to body protein; this latter is then oxidized; the final products being carbon dioxide, water, and various complex nitrogenous compounds such as urea, uric acid, and purine bodies.

The carbon dioxide and water are eventually eliminated as such. The nitrogenous compounds are eliminated by the kidney. During the oxidation of the protein the nitrogen first appears in the form of ammonia; this ammonia is oxidized to urea, in which form it is mainly found in the urine. The non-introgenous part of the protein molecule is believed to be capable of conversion into carbohydrates and fats.

Abnormal protein metabolism. A diet with no protein or with too little protein produces nitrogen starvation, with lower vitality and diminished resistance to infections. A diet containing too much protein has been held responsible for such troubles as gout, arteriosclerosis, nephritis, and various skin diseases; but this contention has not been proved. Autointoxication, following excessive ingestion of proteins, is probably only indigestion. Excessive protein metabolism is believed to occur in case of fevers, infections, intoxications, and some other conditions.

10. The following is from an extended table in Hawke's *Practical Physiological Chemistry:*

Composition of normal blood and of the blood in certain pathological conditions (results are expressed as milligrams per 100 c.c. of blood) unless otherwise indicated:

	Normal.	Chronic Nephritis.	Uremia.	Early Diabetes.	Severe Diabetes.
Total solids, per cent	20 0	13-19	12-18		17 20
Total N, per cent	3.0	2 5-3 0	1.7-2.7		1.8-2 9
Non-protein N	25-35	35 90	90-350		
Urea N	12-23	16 70	70-300		
Uric acid	1-3	1-4	4-27		
Creatinine	0.7-1 3	1-3	4-33		
Creatine	3		5-30		
Amino-acid N	6-8		8-16 0		
Ammonia N	0 1-0 2	0 1-0.2	0 2-1.0		
Sugar, per cent	0.08-0 11		0.1-0.2	0.15-0.30	0 3-0 8
Acetone+ Acetoacetic acid	0-1 0		2-25	1 5-12	10-40
Beta-hydroxybutyric acid	0-3 0		5-25	5-15	10-100
Alkali reserve (c.c. CO_2 in 100 c.c. plasma)	77-53

Miscellany.

Semicentennial of the Discovery by Meyer of Adenoids.—It is almost an axiom that great discoveries are not made by a mere accident in the life of an ordinary man, and a study of the career of such pioneers will usually show that they distinguished themselves in many other ways. In the *Hospitalstidende* for March 26 are numerous reminiscences of Meyer and his discovery. The latter was first described classically in the same periodical for 1868 but was not published in a widely accessible medium until five years later, when Schwartze caused its appearance in the *Archiv für Ohrenheilkunde*. Numerous attempts to claim priority over Meyer have broken down. The discoverer was born in 1824 and died in Italy in 1895. He served as surgeon in the Schleswig-Holstein war and did not begin civil practice until 1853, after having spent two years in the clinics at Berlin, Vienna, Prague, and Bonn. Here he became thoroughly grounded in pathology, microscopy, and chemistry. Not satisfied with Teutonic culture, he studied at Paris. When ready for practice he had been a student of men like Virchow, Rokitansky, Hebra, Skoda, Oppolzer, Claude Bernard, and several well-known analytical chemists. Still unsatisfied, he visited England and Scotland, and in Edinburgh studied diagnosis under Hughes Bennett and obstetrics under Simpson. Few men of his day were better trained in all-around medicine. Singular is the fact that he took no course with the early otologists of reputation. But in 1853, when he began practice, Wilde's book on the ear appeared and apparently awakened his enthusiasm. At any rate, he became a devotee to that organ, but not until 1865 did he have a clinic devoted to otology—whether private or affiliated with Copenhagen University does not appear. For many years he was taken up largely with the subject of adenoids, and examined many hundreds of school children. While active in all other fields of otology, his great impression was made in popularizing the operation of adenoidectomy. In 1888 Morell-Mackenzie computed that (only 15 years after the publication of his paper in the *Archiv für Ohrenheilkunde*) at least 100,000 human beings had submitted to this operation.

Better Babies for France.—In a recent bulletin the American Red Cross tells of the work it has been doing in establishing nurseries for babies under two years of age throughout the devastated districts of France. In this work with mothers and babies the Red Cross is receiving the wholehearted cooperation of the French Government, which is doing everything to encourage maternity. It is giving an allowance of fifty francs a day to women during the last month of pregnancy in order that they may have a chance to rest before confinement. There is also a somewhat smaller allowance made for women who nurse their babies. During their confinement they are given the best of care. When the mothers have regained their strength, their babies are placed in the "creche" conducted by the American Red Cross in conjunction with the town officials. If possible the mother will work near the creche so that she may be able to suckle her offspring.

TREATMENT OF INFLUENZA AND ITS PULMONARY COMPLICATIONS.*

BY J. M. ANDERS, M.D., LL.D.,

PHILADELPHIA, PA.

Prophylaxis.—From the appearance of the earliest symptoms strict isolation should be adopted. This is especially important when an extensive epidemic of malignant type is prevailing in the vicinity or elsewhere. E. W. White has reported an epidemic of influenza that was successfully aborted by strict isolation of the patients. Whilst it is a difficult task to carry out an absolute quarantine, except in children and aged persons, in which cases it should always be done, yet recollecting the undue susceptibility of persons in the age-group of from 20 to 35 years, and also the relatively high death rate at this period of life, isolation becomes a matter of the utmost importance. Among other prophylactic measures of great value is thorough disinfection of the catarrhal discharges, especially the bronchial, and also those from the nasopharynx and mouth cavity.

The wearing of suitable masks by physicians, nurses, and attendants is counseled by many clinicians. Weaver's[2] experiments have demonstrated that gauze will remove bacteria from the air when carried in a moist spray. "The efficiency of the gauze as a filter is in direct ratio to the fineness of the mesh and the number of layers." L. Hill,[3] however, asserts that the wearing of a mask, by raising the temperature and humidity of the air breathed, is against the natural defensive mechanism of the respiratory membrane.

Sahli[4] of Berne regards masks as unfeasible. One of his objections is that the conjunctiva may be a portal of entry for the influenza bacilli and another is that the air forced in and out makes strong currents which sweep the bacterin along. He says that the physician can protect himself against the coughing patient by having the attendant cover the patient's face with a towel or the drawn-up flap of the shirt while he is examining the chest. On examining the throat protecting goggles are worn, as for diphtheria patients.

In this connection it is worthy of note that the balance of testimony speaks in favor of immunity in the vast majority of the cases by an attack of influenza. It is probable at least that those who escape infection during a pandemic have become immunized by an inhalation vaccination. The prevention of droplet infection is of prime importance, hence the patient should be instructed to cough into his handkerchief when not too ill. The washing of the hands of the physician and the public is an important prophylactic measure.

It is not possible to overemphasize the importance of absolute confinement in bed until convalescence is well established. The development of fatal pneumonia as a complication is quite commonly traceable to a premature getting up or exposure to the out-of-door air. Drugs (*e. g.* quinine with or without whiskey, and salicin) have been vaunted for their preventive effect, but in my view their value is questionable. Influenza has quite properly been placed on the list of notifiable diseases in certain leading American cities, *e. g.* New York, Philadelphia, and Chicago.

Recio[5] lauds polyvalent mixed anti-influenza bacterin as a prophylactic. In a group of 300 persons thus vaccinated only five developed influenza during a seyere epidemic, while none of 100 children so treated contracted the disease. Hinaker and Irvine[6] have found that a noteworthy degree of protection against influenza and its complications was obtained by means of a mixed vaccine freshly prepared from predominating etiologic bacteria. With the germs derived from the sputa and secretions in some grave cases, Casabo[7] prepared both a vaccine and a bacterin of which 10,000 doses (four ampules each) were distributed, with most favorable reports of its prophylactic action.

Beihn states that a new vaccine for prophylactic vaccination against influenza pneumonia that holds great promise from a scientific and practical standpoint, is a type of lipovaccine that was originated abroad. Chitmire and Peterson[8], have obtained favorable results with this type in which the organism is suspended in an oil-lanolin. Owing to the slow absorption of the lipovaccines, the entire immunizing dose has been given at a single injection. There is no reaction and the immunity against types I, II, and III is said to be just as good and probably better than the three doses we have heretofore been giving. On the other hand Park states that no data are available as to the effect of vaccine as a preventive or therapeutic measure in true epidemic influenza.

Treatment of the Attack.—Certain hygienic measures including the diet are of first importance in the management of influenza. Cooling drinks are to be preferred to hot ones, and the fluid intake should be large. In cases of moderate intensity and in the severer forms, the diet during the febrile stage should be composed of nutritious liquids, such as milk, buttermilk, orange juice containing

*Read at a meeting of the American Climatological and Clinical Society, Atlantic City, June 14, 1919.

the white of egg, and broths to which strained rice or farina may be added. These should be given at two-hour intervals unless the patient be sleeping. During convalescence soft articles may be allowed for a couple of days and then a return to easily digestible, nutritious solids is to be made in a gradual manner. In mild or rudimentary types, the diet should consist of milk gruels, animal broths, eggs, fresh vegetables, stewed fruits, and the like throughout the brief course of the illness, so as to shorten convalescence.

Free ventilation of the sick chamber is advised, but strong drafts are to be avoided since they produce a chilling effect and thus tend to induce pulmonary complications. The temperature of the room should not be maintained at too low a level during convalescence and cold bath rooms have been responsible for cases of complicating pneumonia at this stage. It is a good rule not to permit the patient to leave his bed until the temperature has been normal for a period of at least four days, except in the light forms of the complaint.

We have reached the point at which all cases showing elevation of temperature, however, slight, are kept in bed until it is back again to normal. These mild types need little else in the way of treatment, if we except careful feeding and regulation of the bowel-function. Active purgatives, however, should be avoided. The writer saw the evil effects of purgatives in many instances during the recent pandemic, the horrors of which will long cling to our memories. During and after the febrile stage in these mild grades of influenzal infection we should aim to promote conservation of energy, and the hygienic and medicinal treatment must have the same objects in view as in the other prostrating diseases. The patient should be allowed to get up for a part of the day only at first owing to the danger of overfatigue from which recuperation is slow and often unsatisfactory.

In the severer forms the temperature may early touch 104° Fahr. During the pandemic of last autumn the fever generally remitted on the second or third day and either remained normal, or more commonly a secondary rise following the remission, accompanied by coryza and bronchitis, occurred. The fever and accompanying symptoms are best controlled by cool sponge baths and the icecap. Quinine in combination with Dover's powder, alternated with a simple antifebrile mixture with the object of inducing perspiration may be prescribed with good effect. An efficient diaphoretic, if given at the onset, may, as I have observed, abort the attack.

The therapy of the febrile stage usually embraces the use of the depressing coal-tar products, which are merely mentioned here to be condemned. In my view, their harmful effects far outweigh their usefulness; they tend to increase the extreme exhaustion of the convalescent stage, not to speak of their marked depressing effects upon the heart's action. On the other hand digitalizing these patients has seemed to me to avert secondary developments, more particularly in the lungs. Experience has made me partial to the view that potassium citrate, administered in 10-grain doses every third or fourth hour well diluted, is useful as an eliminant.

The severe myalgia is often relieved by resorting to aspirin, but I do not favor its employment for this purpose, having witnessed repeatedly the irritable heart with its rapid fatigue on exertion as a sequel, in cases in which it was used. In my view the myalgic pains can be most successfully and safely relieved by the use of small doses of morphine.

Persistent neuralgic headache, with tenderness over the sinuses, points to sinusitis as the cause, which should receive the attention of the specialist. For severe headache, *per se* we may employ caffeine combined with sodium bromide. For the disturbances of the cardiovascular system, nothing is so valuable as absolute rest.

The bronchitis is relieved, to an extent at least, by the potassium citrate suggested above, to which may be added ammonium chloride and terpinhydrate. If the cough be frequent and unproductive, codeine or dionine will exert a happy effect. A most useful measure is the oft repeated application of sinapisms to the entire chest. It is highly probable that there is in all cases of considerable influenzal bronchitis, some lung involvement, varying in degree, however, between the two extremes of small islets of infection to massive consolidations. It is particularly at this stage that acetylsalicylic acid and other depressing agents should not be employed. My own experience has confirmed the value of camphor in oil, strychine and atropine, hypodermically, the latter seeming to relieve the dyspnea and cyanosis, in some cases at least. Epinephrin and pituitary extract and solution have their warm advocates, but my personal experience of their use has been too limited to base thereon any conclusions. On the whole so little improvement is noted from cardiac stimulants as to lead to noteworthy discouragement. Perhaps the most satisfactory results were obtained from the use of camphor in massive doses, say grains 15-30 in sterile oil, intramuscularly. Small and Blanchard[10] experimented with groups of patients—fifteen in each—and concluded that patients treated by gelsemium improved in a manner far exceeding those given any other medication.

In response to a suggestion made early in October, 1918, that immune serums regardless of their nature might be beneficial, Lamb and Brannin[11] made trials of the so-called foreign protein treatment at Camp Cody. They carried out sensitization tests by a small subcutaneous injection of diphtheria antitoxin. "If no indication of anaphylaxis appeared. 10 c.c. were administered by vein. In forty-five minutes a sharp reaction (chill, fever, and sweat) usually began. At the end of from twenty-four to forty-eight hours, if no marked improvement was observed, or if the patient was not moribund, a second dose was given."

These observers also employed antimeningococcic, antitetanic, and antipneumococcic serums, and late in the epidemic the use of a bacterial filtrate was instituted. Their conclusions were the following:

"1. Many cases, which appeared at their onset to be of the malignant type, would after its use show an improvement (often unexpected), with subsequent recovery.

"2. No improvement resulted unless a reaction occurred. For this reason we were partial to the

more concentrated products (diphtheria serum and bacterial filtrate).

"3. The same benefit was derived from the antimeningococcic, antitetanic and antidiphtheritic as from antipneumococcic serum, provided a satisfactory reaction resulted. In other words, there was no apparent specific action of any type of serum, but the result was dependent entirely on its protein content.

"4. Early administration was essential to effectiveness.

"5. No harm, attributable to their use, was ever observed.

"6. While an artificial crisis was desired and anticipated, more often, when benefit did result, it came as a gradual reduction in toxemia."

Herman,[12] in summarizing the subject, concludes that "the intravenous injection of foreign protein serves as a stimulus for the liberation of specific antibodies in animals in which the previously injected antigen was unable to cause such a liberation." Roberts and Cary,[13] after critically analyzing their results, conclude that protein injections have a very definite value and believe that the procedure will come to be accepted as useful in a wide variety of infectious diseases. The point to be borne in mind in connection with this mode of treatment is that while the injection *per se* is not specific, it calls forth a specific response.

Cowie and Beaven[14] have employed typhoid protein in nine cases of influenzal pneumonia with distinctly encouraging results, although in their limited experience, they found that, if used intravenously, it is indicated only in the beginning stage of this disease and that not more than 500 million dead typhoid bacilli should be given at one injection.

A number of clinicians have reported excellent results from the use of vaccines by giving minute doses of 20 million organisms during the febrile stage. On the other hand to be useful the vaccine must contain the special type of organism with which the patient is infected. Again, I quite agree with Beihn that little dependence is to be placed on the vaccine treatment, although when given early in small nontoxic doses it offers better promise than in larger doses.

The most notable advance in specific therapy in this disease has been the injection of the serum of convalescents in the treatment of others suffering from the same type of infection. McLean and Pepper report favorable results from the use of convalescent serum, a physician and a nurse being the first cases. Bacteriological examinations showed that the patients from whom they obtained the serum had influenzal and type IV pneumonic infection. McGuire and Redden[8] are convinced that the serum from convalescent pneumonia patients has a decided influence in shortening the course of the disease and lowering mortality. To determine the type of infection the services of a laboratory, however, are required in each case, and this is not available to the average general practitioneer.

The period of convalescene demands close attention. The marked degree of weakness is shown by the utter exhaustion on the least exertion. Rest, good, easily digested food, and tonics are the agencies of choice in attempts to restore normal strength. Incomplete recovery and a tendency to merge into chronic invalidism is often the consequence of a too early return to work. The usual duties and responsibilities of life therefore, should be resumed in a gradual manner.

PRACTICAL APPLICATION OF THE FACTS OF NARCOTIC DRUG ADDICTION DISEASE.

By CHRISTIAN F. J. LAASE, B.S., M.D.,

NEW YORK

ASSOCIATE SURGEON, ST. MARK'S HOSPITAL; ASSISTANT VISITING PHYSICIAN, ST. JOSEPH'S HOSPITAL.

Narcotic drug addiction has become one of the most important public health questions of the day. Although for centuries the world has been familiar with one phase of the question in the form of opium smoking in the Orient, little advance was made up to very recently in understanding the real nature of the condition and little progress in its control. Opium smoking in this country dates from its introduction with the immigration of the Chinese. Morphine addiction dates from the time of our Civil War, during which a large number of our wounded soldiers became addicts as a result of the necessary administration of opium and its alkaloids to combat the shock and sufferings of the wounds of war. While restrictive legislation has to a certain slight extent curtailed the number of opium smokers, it has had comparatively little effect, opium smokers having been driven to resort to the alkaloids of opium, morphine, heroin, etc., and still a considerable amount of opium smoking is done. The growth of the addiction to these opiate drugs has been so subtle and insidious that it is only within the last few years that the attention of the community has been suddenly precipitated upon a condition affecting an estimated 100,000 to 250,000 people in our city of New York, 500,000 in the State of New York, and about a million and a half in the United States.

Much mystery has prevailed as to the basic nature of addiction. Much misconception and misunderstanding have arisen and are responsible for the harmful, misguided legislative and administrative procedures intended to curb and abolish the condition without, however, having had any influence upon the ultimate solution. Addiction was looked upon as an indulgence for sensuous pleasure, a vicious habit, a depraved taste which could be given up or stopped by the mere exercise of will power. This conception—which is hardly in advance of that held in China for centuries—still prevails in legislative, administrative, and medical circles even up to the present day. Under this conception, an addict was ostracized, shunned in society, treated as a criminal, and clapped into jail or penitentiary where without any help or sympathy extended to him he was permitted to suffer the most excruciating physical and mental torments. And this conception dominated even the attitude of the medical profession toward addicted persons. The great majority of medical men would have nothing to do with addicts; and the results of treatment for the ultimate cure were discouragingly disappointing. Unable to obtain relief from those they thought the logical source of that help and relief—namely, the medical profession—they sought for it elsewhere and became the prey of persons and institutions with an advertised "cure" and especially of illicit underworld criminal peddlers and smugglers. These latter constitute the most serious, menacing, and threatening phase of the whole question of narcotic drug addiction and this traffic has furnished a basis for the most loathsome moral shame of this country—white slavery.

Altogether under this conception the lot of the addict is not a happy one, nor is the future prospect a rosy one.

However, about 20 to 30 years ago a rift in the clouds of mystery and misconception and ignorance pervading the whole question was made by Oscar Jennings of Paris, who, as a result of his clinical observations and experience, propounded the theory that narcotic drug addiction is a disease process, and that addicts are sick persons and should not be treated as criminals or as depraved or defective individuals. Nearly contemporaneously in this country Dr. Petty of Memphis came independently to a similar conclusion and contributed to the advancement in the understanding of this condition. It is only very recently, within the past nine years, that Dr. Ernst S. Bishop of our own city enunciated as a result of his clinical observation and experience in Bellevue Hospital a principle of the mechanism of the production of this condition that is capable of explaining the manifestations and the phenomena that uniformly characterize the condition. Finally laboratory experiments have been performed on animals and these experiments demonstrate that any red-blooded animal may be made and become an addict, and they corroborate most conclusively and convincingly the theory of the mechanism of the production of narcotic drug addiction as enunciated by Dr. Bishop.

Now in order that my readers may follow me I want them to have in their minds a clear picture of an addict. One of the most striking points about an addict is that he can with perfect impunity take such large doses or quantities of the drug which would be positively fatal to a normal individual. An addicted individual after partaking of his drug may not show—even to the trained observer—the slightest indication of the fact that such drug has been taken. He will be no different from ordinary normal individuals; he will go about his business or calling the same as other individuals; he will compete with his normal neighbors and will at times even surpass or outdo them. For all the world he is the same as any other individual despite the fact of his addiction.

Now deprive that individual suddenly and entirely of his drug and the picture will undergo a complete transformation. The individual will become intensely nervous. His hands will tremble; his eyes will begin to water and he will sneeze and sniffle; he will gape and yawn and his gape and yawn are more compelling and intense and prolonged than those of a normal, tired individual. He will cough and choke; he will have severe pains in the legs and all over the body; he will become so weak that his legs cannot support him; he will fall down on the floor and writhe in pain and convulsion. He will retch and vomit and it is surpri ing the quantity of material he will bring up from his stomach; he will get the most intensely painful cramps in his abdomen at the same time, doubling up like a jackknife from the pain. The face will become pinched and drawn and ashen in hue like a death mask; cold perspiration rolling off his body, pupils widely dilated, further prolongation of the agony will lead to collapse, and even death has ensued. Suicide has often terminated the extreme agony.

And it is not even necessary to deprive such an individual entirely of his drug to produce such suffering, agony, and torment. It is only necessary to deprive him of a portion of the usual amount taken to produce signs and symptoms of distress and suffering of such a degree as to render him unfit to work or to follow his vocation or competently to perform the duties of that calling.

No matter how the opiate drug is used; no matter what form is used, such is the picture produced on withdrawal or partial deprivation of the drug. These signs and symptoms are constant, uniform, recurring manifestations and phenomena under these conditions, just as constant, uniform, and recurring as are the signs and symptoms of a disease like pneumonia or typhoid fever. These physical and mental pains and sufferings are so excruciating that they have been compared with the conceptions of hell and they have been described as being infinitely worse than the pains and sufferings of acute attacks of gallstones or kidney stone colic—agonizing as these conditions are.

Now take an individual in this condition of withdrawal or deprivation, even in a condition of fatal collapse as if in impending dissolution; give him a dose of opiate drug and a most astounding transformation will take place. From this condition of apparent impending dissolution, the individual will rise and go about his business as if nothing had happened—apparently as normal and as strong as any other individual.

The relief from these excruciating sufferings obtained by recourse to the opiate is so prompt, so swift, so certain, so complete that an afflicted indi-

vidual will go to almost any length to obtain the drug; and it has been said that "if all addicts were confined to an island with swift running currents about it filled with floes of ice, and a ship laden with the opiate brought to anchor in the stream and word given to the addicts that they could have their drug on condition of swimming out to the ship, not a solitary one of them would hesitate to brave the turbulent icy waters in a desperate try to reach that ship."

What is it? What is the nature of the condition we are dealing with? It has been called and considered a "habit," a vice, a depraved taste, accompanied by sensuous pleasure, a matter of the mind; but this conception does not satisfactorily explain the abject sufferings, the apparent dissolution just described. They have even been considered as exaggerations, figments of the imagination, subterfuges to obtain the drug. It does not satisfactorily explain that urge, that drive for the drug which corresponds in intensity and impulse to the urge, the drive for food and drink that characterizes the individual who is starving, accompanied with indescribable, unbearable physical tortures. Any explanation of these phenomena based on this conception of a vice or habit leaves the mind of an intelligent individual "high up in the air." And this conception furthermore does not explain the occurrence of drug addiction in the newborn. For it is a fact well known among those who have given attention to the subject that a baby born of an addicted mother is itself an addict, evidencing the same manifestations and phenomena as the mother; and it is also a well-known fact that unless opiate is administered to that child it will die. Surely no one is justified here in speaking of mind or will or vice or habit.

Now I have said that a few independent thinkers and observers, casting aside accepted opinions and conceptions, made independent clinical observations and performed independent laboratory research work which have thrown considerable new light upon and contributed greatly to the understanding of the nature of drug addiction. I will not mention all again in detail. I will only call attention to the work of Dr. Bishop and of Valenti in Rome; each and both of them taken together have said the last word so far in drug addiction. Dr. Bishop as a result of his clinical observations and experience in Bellevue Hospital eight to nine years ago enunciated the principle that due to the continued administration of narcotic opiate drugs a protective mechanism against the toxic effects of the opiate has been set in motion within the body, that by virtue of this mechanism certain protective and antidotal substances—which we may call antitoxins or antibodies for want of a better name—have been formed and are floating in the blood; that these protective substances are themselves toxic or poisonous when circulating free in the blood and that these free, uncombined protective substances are the cause of all the physical manifestations of suffering and distress that characterize the withdrawal or deprivation of the drug. This conception is conclusively corroborated by the laboratory experiments of Valenti of Rome performed and reported shortly before the beginning of the war. In these experiments dogs of about equal weight were taken in pairs. One of each pair received daily injections of morphine in increasing doses over a period covering several months, until very large doses were administered with impunity. The other dog received none, but otherwise the two dogs of each pair were kept under similar conditions. When the first dog had come to tolerate large doses of the drug which would have been fatal to a normal dog, the drug was entirely withdrawn and the dog at once began to show signs of distress and suffering that correspond to those characteristic of the human being during withdrawal. Studies were especially made upon the heart and circulation and the effects upon them of the withdrawal of the drug were accurately measured by instruments of precision. Then during this stage of withdrawal of the drug, blood was drawn off from the veins of the dog that had received the morphine and the serum was injected into the veins of the dog that had received no drug; and lo and behold, this dog displayed the same signs of distress and suffering as the other dog after withdrawal of the drug. The effects upon the heart and circulation were measured by the same instruments of precision and they were found to correspond in degree and severity with those noted in the morphinized dog. Administration of the drug abated all the suffering and returned both dogs to their previous condition.

Dr. DuMez of the United States Public Health Service, in a review of the literature on the subject, points to the observations and conclusions of Dr. Bishop and the work of Valenti and draws the conclusion that evidently there is present in the blood of tolerant animals during periods of abstinence a substance or substances which when injected into normal animals of the same species causes the appearance of symptoms identical with the so-called withdrawal phenomena."

Now I want the reader to get this. It is going to help him understand the meaning of the whole thing and he will even be able to draw his own conclusions as to what ought to be a practical application of the facts of addiction.

Substances floating in the blood—antidotal substances, antitoxins, antibodies—call them what you will—protect the organism against the toxic action of the drug itself and enable the body to tolerate enormous quantities of the drug; and yet when the drug is withdrawn, leaving these antidotal substances free and uncombined, the latter are themselves poisonous to the body and produce the abject sufferings of the addict when deprived of his drug. The addict takes to the drug to neutralize these antidotal substances—but he doesn't know it—all he knows is that the drug will keep away those pains that we now know are caused by the antidotal substances. And he doesn't take the drug for the pleasure of it or the satisfaction of it; but because on account of these antidotal substances there is a real body need for it. So we can see that the mind has nothing to do with it. It is beyond his control! It is beyond his will power.

These are facts—facts which cannot be denied, and they overthrow all the old theories and conceptions of drug addiction. It is no longer justifiable to speak of drug addiction as being a habit, a vice, a degeneration or perversion of the mind. It is a distinct, definite physical disease condition with definite uniform manifestations and phenomena and

a definite understandable causation. And it is not for this reason the function of legislators or courts or police or other officials to take charge of or to direct what shall be done. Taking care of the sick is solely the function of the medical profession and it is to the medical profession that we must look for the ultimate solution of the whole question.

Ignorance of the real nature of drug addiction, ignorance of the real facts of drug addiction, has been fundamentally the cause of its widespread extent among our population to-day. Bishop and others have reiterated this in their writings for years. It was ignorance of these facts that led communities to permit low dens and gilded palaces to flourish where opium smoking produced its victims as it had done for centuries in China under the mistaken idea that it was a harmless pastime that could be given up any time. It was ignorance of these facts that permitted gullible, adventurous youths of both sexes to partake of a white snuff under the same mistaken idea, offered in ignorance or by design. It was likewise ignorance of these facts that permitted medical men to carry on the administration of narcotic drugs over an undue period and permitted patients of their own accord to do the same. And it was also ignorance that led to the persistence among medical men of the old conception of drug addiction and the consequent neglect of study of the condition, neglect of the addict and resultant ill success that has characterized the treatment and care of the addict up to the recent date.

Thus we have one clear indication for the practical application of these facts of addiction and that is *education*. Education by publicity and every other way of legislators, courts, police, and other administrative officials, including even the Health Department, which could make itself so useful instead of exerting that baneful influence, creating panic, that characterizes its activity to-day. It has immense laboratory facilities where it could investigate still further and more completely these facts of addiction, and it has immense facilities for the education of the public in general and of the medical profession in particular, but so far nothing of value has come out of either. Knowledge of these facts of addiction would deter many an intending smoker from yielding to the blandishments of his tempter or temptress, either innocent or guilty of nefarious design. A young man or young woman knowing the positive ultimate results of continuing to yield would surely hesitate a dozen times before taking chances of implanting within the body the seeds of a physical disease with such dire consequences of agonizing suffering and enslavement. Such a campaign of education in itself would tend greatly to curtail the spread of the affliction.

Much is made of the existence of ten thousand addicts of a criminal nature in New York. We hear much from reformers, correctional officers, police, alienists and physicians connected with various institutions of penology, custody, and correction who have made observations upon the criminal, vicious, irresponsible, defective, and degenerate individuals coming in their control in whom addiction disease has developed; and they have applied the morbid and spectacular manifestations of these types to the entire body of addicts in general; and we hear from them loud and strenuous recommendations of finger-printing, mugging, branding among the methods intending to force them to give up the use of the drug. Sight is lost of the fact, however, that these ten thousand form only a small percentage of the total number of addicts we have in this city—estimated at from 100,000 to 250,000. Sight is lost of the fact that the 90 to 95 per cent. of these addicts constitute individuals in every walk of life—from the highest to the lowest—honest, useful citizens of the highest repute who, through unfortunate circumstances, through no fault or will or intent of their own, have developed the condition of narcotic drug addiction disease within their own bodies. There are among them ministers, judges, lawyers, doctors, scientists, mechanics, artisans in the industries, the munition plants, the army and navy. Even the successful conduct of the war has to an appreciable extent been dependent upon their efforts. Finger-printing, mugging, branding will not prevent the spread of addiction among them; but it would work the greatest amount of harm among these 95 per cent.—as long as the characteristics of the criminal and the defective and degenerate addict are wrongfully made the characteristics of all. These procedures would render the honest, useful addict open to blackmail and publication of the fact of addiction in any way would subject him to social, economic, and financial distress.

These hundreds of thousands of useful, honest addicts are crying for help and relief. They do not need such measures to force them away from the use of the drug. All they want is considerate, sane, humane handling and treatment such as is due to sick people; and they will flock in droves to undergo any bearable treatment which holds out to them a reasonable hope of ultimate relief from their affliction.

The investigation before the Whitney Committee has shown the results of treatment to have been discouragingly disappointing. The results of treatment in our public institutions have been characterized by the Chief Magistrate of our police courts as having as much influence upon the addiction condition as spitting in the Atlantic Ocean has upon the tide. The much advertised "cures" have been shown in the Whitney investigation testimony and elsewhere to be highly commercialized exploitations of the unending hopes of the addict. This has been because all these failures in results have been based upon the old conception, the old ideas of habit, vice, and so on, and the real basic nature of the condition not recognized. Yet the experience of Dr. Bishop and others has conclusively demonstrated that drug addiction disease, treated according to the modern conception, is certainly and definitely controllable and curable.

Up to the present, our large semiprivate charitable hospitals would have nothing to do with the treatment and care of addicts and have even refused admittance to sufferers from pneumonia or grippe or people requiring operation who happened likewise to be suffering from addiction. For the ultimate solution of the problem, the services of these institutions are absolutely necessary for further study and investigation and to help care for some of the 200,000 sufferers—a number far too large to be accommodated by even all of our penal and correctional institutions, even if their treatment in such institutions were desirable. But physicians

educated and trained under the newer light, the newer conception, are lacking—so likewise are nurses lacking. It takes time to have these hospitals enter upon this work and it takes time to train the doctors and the nurses. And in the meantime the addict must have the drug that will keep him from the agonizing sufferings described in the earlier part of this article. The only logical source through which the addict is to obtain this drug is the doctor. This was the consensus of opinion of experienced and official testimony before the Whitney Committee; and the committee urged and encouraged the medical man to enter upon the work of caring for the addicts; and especially the officials of the United States Internal Revenue Service encouraged them to do so, because it was thought doing so would greatly reduce the serious menace of the illicit traffic in the drug by the criminal underworld. Physicians did enter upon this work of attending to the needs of the addict, and the illicit underground traffic was almost entirely wiped out. But there is another very important reason why physicians should enter upon this work. The physician is brought into direct contact with the addict. He has thus opportunity to study the patient himself and his disorders, the effects and action of the drug taken, the effect and action of various remedies, and the reaction of the patient to them all, and he could study the methods and frequency of administration and in time would learn to correct the faults he found. In time he would in this way accomplish a great deal of good for the benefit of his patient, more so than is generally believed by penal, correctional, and other officials, and this good is in the direction of accomplishing a definite utlimate cure. The treatment accorded the addicts in the Department of Health does not come up to this ideal. That of an addict patient consists of a good deal more than prescribing the drug in diminishing doses in a routine, mechanical way without reference to other elements of moment, such as frequency of dose, elimination, diet, and so forth.

The trouble is that not enough physicians have entered upon this work of caring for the addict. Reports have it that fifty to one hundred have responded to the appeal of the authorities. There ought to be thousands of doctors to do this work—the same as they do in caring for those sick with typhoid or pneumonia or influenza. It is the only way in which a real impression may be made upon the condition and the only way in which we may obtain experienced physicians to take care of the addict patients when more and more hospitals open their doors to this class of patients for their ultimate cure. True, certain evils may have sprung up in connection with doctors caring for the addict by so-called ambulatory treatment; but as Judge Collins has emphatically declared, these evils are not to be compared in seriousness of menace and danger to the community with those of underworld traffic and peddling which cannot be controlled. Nothing therefore should be done to discourage the doctors from undertaking the treatment of the addict in increasing numbers, for such restriction would only encourage the criminal traffic. This in truth has been the effect of the unfortunate publicity—fostered by the attitude and statements of the Health Commissioner.

Conclusions.—Narcotic drug addiction is a definite, physical disease condition—not a habit or a vice.

A narcotic drug addict is not a criminal or a degenerate or defective individual, but is a diseased person entitled to all the humane and considerate treatment and handling accorded to any other diseased person. A criminal addict is a criminal because he is a degenerate or defective of a criminal nature, in whom drug addiction disease has been implanted ofttimes through no will or fault of his own, and he is therefore also entitled to the same humane treatment accorded any other sick criminal.

Education in the knowledge of the facts of narcotic drug addiction disease is a most important factor in the prevention of the spread of the diseased condition—likewise in the treatment and cure of these sick people. And it is also important for the proper understanding of the real nature of the condition so that legislators and administrators may frame and carry into effect reasonable laws and measures calcualted to improve these conditions.

Narcotic drug addiction disease is definitely and positively clinically controllable and curable. More hospitals and more doctors are needed for the care and treatment of drug addicts, and they should be encouraged to enter upon the work.

Finally, our great organization with its manifold branches and ramifications throughout this land can exert a powerful influence in bringing about a better understanding of the nature of drug addiction and the needs of the addict—educating the public, enlightening the legislators and the administrators, calling upon them for sane and reasonable laws based upon the newer light; and calling upon the hospitals and the medical profession for a more determined effort along these lines.

169 West Eighty-fifth Street.

SOME STATISTICS OF INFLUENZA.*

By FREDERICK L. HOFFMAN, LL.D.,

NEWARK, N. J.

THIRD VICE-PRESIDENT AND STATISTICIAN OF THE PRUDENTIAL INSURANCE COMPANY OF AMERICA.

The results of our recent investigations are presented to the members of the American Medical Association in fifty charts which have been reproduced in miniature from the originals shown in the scientific exhibit of the Association. In these charts an attempt is made to visualize the more important facts of an extremely involved mortality problem. No mere analysis of statistics can lead to really useful results; only a graphic exhibit can clearly visualize the correlation of influenza mortality to season, age, sex, race, locality, etc., in a manner likely to suggest some new or heretofore unrecognized truth of what is certain to be one of the most important mortality problems of the future. There is no satisfactory definition of influenza, and experience has shown that the complications resulting therefrom are more fatal in their consequences than the disease itself as a primary cause of death. As far as practicable I have followed the study in comparative statistics of epidemic influenza by F. A. Dixey, M. A., D. M.,

*Read before the Section on Public Health and Preventive Medicine of the American Medical Association, at Atlantic City, N. J., June 12, 1919.

issued by the Clarendon Press, Oxford, 1892. It is realized that even though the fifty charts presented to the Association represent probably the most comprehensive graphic exhibit in standard form ever made of a single disease in the history of medicine, many more charts will be required before the facts of influenza mortality, and its complications, with a due regard to age, sex, season, etc., can be thoroughly understood. It is hoped, however, that an opportunity will present itself in the near future to supplement the exhibit now made with additional charts emphasizing special aspects brought forward by the discussions of influenza mortality at the present meeting of the American Medical and kindred associations.

Any effort concerned with the causation of disease must necessarily take into account the problem of causation itself. There is much guesswork opinion widely at variance with data which cannot be too strongly condemned as amateurish and grossly misleading. In a remarkable essay—"On Causation, With a Chapter on Belief"—Dr. Charles A. Mercier, the distinguished author of works on "A New Logic"; "Conduct and Its Disorders"; "A Text-Book of Insanity"; "Psychology, Normal and Morbid," etc., contributes an illuminating discussion to the causes of death, which should be read by all who may essay upon the so-called causes or conditioning circumstances of influenza. It must be sufficient for the present purpose to merely quote Dr. Mercier's remark that "Mill's whole treatment of the problem of causation is a most deplorable muddle, and that he should have been regarded as an oracle for two generations is a startling proof of the poverty of critical acumen and philosophic insight that has prevailed since his logic appeared." Thus the canons of causation generally relied upon in philosophical thought are ridiculed and set aside by an irrefutable logic and suggestions for reform. Problems as to the causation of death from specific diseases are stated by Mercier as follows:

> The cause of death is always a function of two variables—the power acting to maintain the unchange that we call life, and the action or actions that increase the work that the power has to do. To recur to the simile of the clock, the time of death depends on the amount of resilience left in the spring and the amount of friction in the works that must be overcome. If this friction is materially increased at more than one place in the train, then each increase is a separate cause of the stopping of the clock. The less the power or means of living, the less interference with the processes of life necessary to bring life to an end; the greater the life-worthiness, the more powerful must be the interference necessary to cause death.

Obviously no conclusions can be sound or far-reaching unless more or less in conformity to this method of rigorous thinking and correct interpretation. Influenza is held to be an acute infectious disease due to the *Bacillus influenzæ* originally discovered by Pfeiffer. The vast experience, however, which has been had during the recent epidemic seems to suggest that even though the Pfeiffer bacillus be the cause of certain forms or types of influenza, it is not, or may not be, the causative factor of death in others.

Describing acute tracheobronchitis, it is pointed out by Dr. Frederick T. Lord, author of a treatise on the "Diseases of the Bronchi, Lungs, and Pleura," that:

> An important cause in this group is *influenza*, the prevailing picture of which in all epidemics has been that of a respiratory infection, affecting for the most part the upper parts of the tract as a rhinitis, but in the more severe cases extending to the deeper parts and even into the smallest branches of the bronchi. Not a year has elapsed since the great pandemic of 1889-90 without local outbreaks in some part of the world. The relation which isolated and small groups of infection with acute respiratory symptoms occurring in interepidemic periods bear to epidemic and pandemic influenza is an interesting question which cannot yet be regarded as settled. It is certainly reasonable to assume that in some form the infecting organism in epidemic and pandemic influenza must be kept alive during the interepidemic period, and the contagious character of and the similarity of the symptoms in the severer types of the primary acute respiratory infections suggest that these and the influenza cases may be due to a common cause. So far as the influenza bacillus is concerned, it must be regarded as an important infecting agent in a large number of acute and chronic disturbances during the interepidemic period, and as a contributing factor in many other cases when mixed with the pneumococcus, pyogenic cocci, *Micrococcus catarrhalis*, and other organisms. The cases in which it exists as a practically pure infection present no striking or consistent difference from the respiratory infection with other organisms and without association with influenza bacilli. The organism behaves in this respect like any other of the common respiratory parasites. In the interepidemic period the clinical diagnosis of "influenza" often fails of confirmation by the finding of influenza bacilli in the sputum.

The perplexing confusion is merely increased by statements like those of Dr. R. W. Allen in his treatise on "The Bacterial Diseases of Respiration, and Vaccines in Their Treatment," in which it is said that:

> The *B. influenzæ* produces the most protean symptoms, but it must be borne in mind that usually associated with it is the pneumococcus. An attack of true influenza is usually ushered in by extreme malaise, headache, joint and muscle pains, and pyrexia, perhaps with rigors. Before any respiratory symptoms have developed considerable upset of the digestive system may be produced, while the nerves may be so involved that neuritis, diffuse or local, or herpes zoster may appear. In such instances the infection is probably a systemic one, subsequently to be localized in the pulmonary tissues. Sometimes infection is confined to the nasal passages and their adnexa, and does not extend to the lower respiratory tract; in these instances infection of the antrum, of the ethmoidal, frontal and sphenoidal cells, and of the Eustachian tube is very common, and while in the majority of instances chronic infection thereof does not result, in a by no means inconsiderable number chronicity does ensue.

Equally suggestive is the statement by Dr. A. P. Beddard, in Allbutt and Rolleston's "System of Medicine," where, with special reference to bronchial pneumonia, it is said that, "The *primary diseases* to which bronchopneumonia is most often secondary are measles, whooping-cough, and bronchitis of the larger tubes; less frequently diphtheria, scarlet fever, acute gastroenteritis, enteric fever, *and influenza*. In regard to influenza, as has already been pointed out, it is probable that many cases which appear to be primary are really influenzal."

Pertinent to this discussion are the views of Dr. P. H. Pye-Smith, in the same work, who, with special reference to lobar pneumonia, remarks that, "In adults, influenza is generally considered to be the disease which most frequently simulates lobar pneumonia. Influenzal pneumonia is either a disseminated pneumonia or a bronchopneumonia, and differs from lobar pneumonia both in its clinical

course and in the physical signs. A lobar pneumonia following influenza has generally been found to be caused by the pneumococcus."

In addition to the foregoing, the views of Dr. Wade W. Oliver, Professor of Bacteriology, Long Island College Hospital, may be quoted. He remarks that, "Following the great pandemic of 1890-92, in which persistent search failed to show the presence of Pfeiffer's bacillus, although other germs, such as the streptococcus, were found almost, if not quite, as constantly in the sputum of influenza patients, germs which had as much or as little scientific license for being considered the cause of the disease as did the bacillus championed by Pfeiffer, we are given a curiously pertinent insight into the not infrequent orthodoxy of science." It is in aid of the cause of truth that *The Prudential* gives publicity to the results of its scientific research into the statistical facts of influenza frequency, not only as observed during the recent epidemic, but also during the great pandemics of the past.

Foremost of the former pandemics, the data of which are of present value, is the outbreak of 1845-48, or, in a more limited sense, of 1847-48, which afflicted England, and particularly the city of London. The most useful descriptive account of this epidemic is the one by Dixey previously referred to. The following remarks from his work, however, will be sufficient for the present purpose:

> In the epidemic of 1847 the most noticeable departure from the normal mortality is that shown by bronchitis, the deaths from which were in the maximum week no less than 779 per cent. above the average. Pleurisy follows with a maximum excess of 367 per cent.; asthma with 258 per cent.; pneumonia, 181 per cent.; heart disease, 135 per cent.; phthisis, 48 per cent. The highest percentage excess reached by "all causes" was 135. In considering the figures for this epidemic, it must be remembered that they are to a certain extent vitiated by the system that then prevailed of dividing the average for the quarter equally among its constituent weeks, the result being that the apparent departure from the mean will often give a very inexact impression of the real amount of the rise or fall. This especially applies to the mortality from bronchitis. Nevertheless, after full allowance is made for this source of error, the figures remain sufficiently striking.

The fact must not be overlooked, however, as pointed out by Dr. Dixey, that in 1847 the influenza figures, in the words of Dr. Farr, "include nearly all the cases in which influenza was returned, whether as primary, or secondary, in conjunction with other diseases." In 1890, however, the author states, "only those cases are included in which influenza was returned as the primary cause." Extreme caution is therefore necessary in comparing statistics of the past with the present, since important changes in death classification, tabulation and analysis have been introduced during the intervening years. Comparing the nonepidemic period of 1845-46 with the epidemic period 1847-48, the chart clearly shows the excessive mortality from influenza at the older ages, and also particularly from bronchitis. The death rates from pneumonia considered by divisional periods of life remain almost the same. In all of the charts in which a comparison is made of the mortality from influenza and certain specified acute respiratory diseases the mortality from all diseases of this group almost invariably show a material rise during years of influenza occurrence in epidemic form. A careful review of the mortality of selected localities, or, in other words, those for which the data are sufficiently trustworthy, reveals a striking nonconformity or absence of a clearly defined periodicity, etc., in influenza outbreaks in epidemic form.

The two charts exhibiting the mortality from influenza in New York City during the period 1889-1918 are especially suggestive. They show an entire absence of influenza deaths during the first eleven months of 1889, but a sudden rise reaching epidemic proportions during January, 1890. Following this outbreak there was almost a complete disappearance of influenza deaths until March, 1891, the disease again reaching epidemic proportions during the early part of April. After May the disease practically ceased to occur in New York City until December, 1891, when, beginning with a slight rise of mortality, the disease once more reached epidemic proportions during January, 1892. Thus the course of the disease can be traced during the entire thirty years, or until 1918, when, following a period of nearly ten years of only occasional occurrence, but never rising to the proportions of a serious epidemic, with the possible exception of a suggestive outbreak during the early part of 1916, the disease reappeared during the last week of September, 1918, and reached its maximum proportions during the fourth week of October. It may be questioned whether the history of medicine and statistics reveals a more suggestive illustration of the serious error of relying upon so-called *experience* as a safe forecast for the future. Anyone reviewing the influenza mortality statistics of New York City for the last sixteen years might well have reasoned that the disease in epidemic form had practically ceased to exist, although the comparatively slight outbreaks during the early part of 1916, 1917, and 1918 were all suggestive of a danger practically disregarded by both the public health authorities and those engaged in the practice of medicine as a healing art.

The close interdependence of influenza and other respiratory diseases fails to suggest their relative importance in public health administration, and heretofore not even pneumonia has received the required amount of highly specialized consideration. The charts for New York City illustrate important variations in the mortality from pneumonia which may possibly serve as a suggestive index of future outbreaks of influenza. Apparently the mortality from bronchitis was not seriously affected in New York City by the enormous increase in deaths from pneumonia and influenza, as best shown by the chart exhibiting the facts of the epidemic period 1918-19, first for influenza and nontuberculous respiratory diseases combined; and second, for pneumonia and bronchitis. The same conclusion applies to the chart illustrating the age distribution of the mortality in New York City from certain specified causes, or, in detail, for influenza, bronchitis and pneumonia. In this chart an effort is also made to compare the age distribution of deaths from causes stated during the epidemic years 1890-91 and 1918. It is shown that profound alterations in the age distribution of deaths from influenza occurred, but there were no very important changes in the mortality from bronchitis. The

proportion of deaths from pneumonia decreased quite considerably at the younger ages under five, increasing, however, materially at ages 25-44.

A comparison of the monthly death rates from influenza and pneumonia on the basis of the data for the State of Massachusetts, for the periods 1887-92 and 1914-19, also reveals the extraordinary inconsistency in the groups, suggestive of the probability that the epidemic of 1918 was essentially at variance in its main characteristics with the epidemics of the past.

In Massachusetts, however, the mortality from bronchitis reached a maximum point during the year of greatest frequency of influenza in 1892, but there seems to have been no such increase in the mortality from bronchitis during 1918.

Even more remarkable, however, are the statistics of the mortality for four American cities, which in certain cases show an extraordinary consistency or similarity, but in others a wide degree of divergence. In Dayton and Columbus the disease recurred in serious epidemic form during October, 1918, culminating in a second outbreak, practically equivalent in seriousness to the first, in the month of December. In contrast it appears that in Pittsburgh there seems to have been no such recurrence, and in Cleveland the rate of maximum frequency during the first epidemic was not attained again during the second.

These are merely illustrations of the charts which have been made aavilable for the information of the medical profession, and of which copies can be had on application to *The Prudential*. Those who may wish to reproduce the charts will be provided with electrotypes, and we hope to be able to furnish lantern slides to those who can use such reproductions for lecture purposes.

It is conservatively estimated that the mortality from influenza and pneumonia caused a loss last year of approximately 400,000 lives. If allowance is made for the normal mortality which would have occurred from bronchial and other forms of pneumonia, and other diseases complicated by influenza, the excess in the mortality was certainly not less than 300,000. On the basis of a conservative estimate the normal death rate was increased 20 per cent. by the influenza epidemic. Further study and analysis of the available data concerning influenza is therefore urgently called for by the vast importance of the disease to the American people. It is a foregone conclusion that there will be a recurrence of the epidemic, the severity of which will depend largely upon its collateral effects upon other diseases.

As observed by Dixey, "Among the disorders the mortality from which is carried up with the rise of influenza, those of the respiratory system, especially bronchitis and pneumonia, hold the leading place. Phthisis also and diseases of the organs of circulation, was largely affected, while the number of deaths attributed simply to old age undergoes a marked increase. Dr. Farr has pointed out that the epidemic of 1847, besides being fatal to the 'asthmatic', caused a rise in whooping-cough, measles, and typhus. . . . It has been asserted that the prevalence of influenza has at least in some cases led to a large increase in the number of deaths due to premature birth." The epidemic of influenza and its numerous resulting problems clearly emphasizes the importance of a new system of death classification, which shall include at least the secondary causes of death. The so-called Budapest system of death classification offers the only solution of a difficulty which will continue to perplex those who desire to know the whole truth of the influenza problem. The adoption of the Budapest system of dual classification is neither difficult nor expensive, but once in general use, will aid materially the whole cause of preventive medicine, public health, and medicine as a healing art. These and many other improvements in statistical practice are urgent requirements for an understanding of disease prevalence and disease causation which is to bring us nearer to the ultimate truth.

Of special value in connection with the foregoing is the following concluding sentence from an exceedingly important report on "Pneumonia in Army Camps," by Dr. William G. McCallum, issued under date of April 16, 1919, by the Rockefeller Institute for Medical Research.

Referring to the Significance of the Presence of Influenza Bacilli in Pneumonia, it is said:

> Whatever its true status in connection with the epidemic disease, influenza, we have at least learned from numerous autopsies that it must be regarded as a serious pathogenic agent in the production of pneumonia, and that it may be found in pure culture associated with a form of pneumonia which is practically identical with the interstitial bronchopneumonia described above, except in the absence of empyema. It is, however, often found with pneumococci and streptococci in other types of pneumonia. I think it must be recognized that the interstitial forms of bronchopneumonia can be produced by various organisms, including pneumococci, streptococci, and the influenza bacillus. where there is a mixed infection it is difficult to assign to each its exact part in the process, but it appears that, in spite of the frequent presence of the influenza bacillus, this was essentially an epidemic of streptococcal pneumonia.

Thus one scientific investigation after another finds a solution of the correct question only further removed. As pointed out in an account of the "Origin, Symptoms, and Cure of the Influenza or Epidemic Catarrh," published in Philadelphia in 1832, "It is to the dread of the disease, of its vagueness and obscurity, that every effort to elucidate the facts of influenza occurrence in epidemic form are a welcome addition to the ultimate cause of truth." There is as much danger in the ready acquiescence to influenza occurrence as in the fatalistic attitude regarding other disease factors common to modern life.

Dr. Peter Irving, in an essay entitled "An Inaugural Dissertation on Influenza," published in the City of New York in 1794, introduced the subject with what properly makes a concluding sentence to these few remarks:

"It is an old and well-established adage, that custom reconciles all things. The universal prevalence of evil has long since habituated the world to its uncomfortable effects. Disease itself, though always an unwelcome visitor, has become an old acquaintance; and those complaints, not generally fatal, which are most common, are at length so familiarized to our ideas by the frequency of their occurrence that, while absent, they are rarely dreaded and, when felt, are commonly disregarded."

List of Charts.

The following is a list of the charts on influenza and respiratory diseases, exhibited in the Scientific Exhibit of the American Medical Association, Atlantic City, N. J., June 9-13, 1919, by The Prudential Insurance Company of America, Newark, N. J. A complete set of these chart reproductions may be had free of charge on request:

Nine American Cities—Epidemic Period of 1918. Mortality from Influenza, Pneumonia, and Influenza and Pneumonia Combined, by Age and Sex.

Four American Cities—Epidemic Period of 1918. Mortality from Influenza and Pneumonia by Race and Age.

New York City—During the Years 1890-1891 and 1918. Proportionate Age Distribution of Mortality from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined.

England and Wales—During the Epidemic Years 1847-1848, 1890-1892, 1898-1900 and 1918. Proportionate Age Distribution of Mortality from Influenza.

England and Wales—During the Epidemic Years 1847-1848, 1890-1892, 1898-1900 and 1918. Proportionate Age Distribution of Mortality from Influenza and Nontuberculous Respiratory Diseases Combined.

England and Wales—During the Epidemic Years 1847-1848, 1890-1892, 1898-1900 and 1918. Proportionate Age Distribution of Mortality from Pneumonia.

England and Wales—During the Epidemic Years 1847-1848, 1890-1892, 1898-1900 and 1918. Proportionate Age Distribution of Mortality from Bronchitis.

New York City, London and Paris—Epidemic Period 1918-1919. Weekly Death Rate from Influenza.

New York City, London and Paris—Epidemic Period 1918-1919. Weekly Death Rates from Influenza and Nontuberculous Respiratory Diseases Combined.

New York City—Epidemic Period of 1918-1919. Weekly Death Rate from Influenza, and Influenza and Nontuberculous Respiratory Diseases Combined.

New York City—Epidemic Period of 1918-1919. Weekly Death Rates from Pneumonia and Bronchitis.

London, England—Epidemic Period of 1918-1919. Weekly Death Rates from Influenza, and Influenza and Nontuberculous Respiratory Diseases Combined.

London, England—Epidemic Period of 1918-1919. Weekly Death Rates from Pneumonia and Bronchitis.

Paris, France — Epidemic Period of 1918-1919. Weekly Death Rates from Influenza, and Influenza and Nontuberculous Respiratory Diseases Combined.

Paris, France — Epidemic Period of 1918-1919. Weekly Death Rates from Pneumonia, Bronchitis, and Other Respiratory Diseases.

North Atlantic Cities—Epidemic Period of 1918-1919. Weekly Death Rates from Influenza and Pneumonia.

Middle Atlantic Cities—Epidemic Period of 1918-1919. Weekly Death Rates from Influenza and Pneumonia.

Central New York Cities—Epidemic Period of 1918-1919. Weekly Death Rates from Influenza and Pneumonia.

Upper Ohio Valley Cities—Epidemic Period of 1918-1919. Weekly Death Rates from Influenza and Pneumonia.

Lower Ohio Valley Cities—Epidemic Period of 1918-1919. Weekly Death Rates from Influenza and Pneumonia.

Upper Mississippi Valley Cities—Epidemic Period of 1918-1919. Weekly Death Rates from Influenza and Pneumonia.

Southern Cities—Epidemic Period of 1918-1919. Weekly Death Rates from Influenza and Pneumonia.

Pacific Coast Cities—Epidemic Period of 1918-1919. Weekly Death Rates from Influenza and Pneumonia.

New York City—1889-1913. Weekly Death Rate from Influenza.

New York City—1914-1918. Weekly Death Rate from Influenza.

New York City—1889-1898. Weekly Death Rates from Influenza, and Influenza and Nontuberculous Respiratory Diseases Combined.

New York City—1899-1913. Weekly Death Rates from Influenza, and Influenza and Nontuberculous Respiratory Diseases Combined.

New York City—1914-1918. Weekly Death Rates from Influenza, and Influenza and Nontuberculous Respiratory Diseases Combined.

New York City—1889-1903. Weekly Death Rates from Pneumonia and Bronchitis.

New York City—1904-1918. Weekly Death Rates from Pneumonia and Bronchitis.

Massachusetts—1868-1918. Annual Death Rate from Influenza.

Massachusetts—1868-1918. Annual Death Rates from Influenza, Pneumonia, Bronchitis, and Influenza and Nontuberculous Respiratory Diseases Combined.

Massachusetts—For the Periods 1887-1892 and 1914-1919. Monthly Death Rate from Influenza.

Massachusetts—For the Periods 1887-1892 and 1914-1919. Monthly Death Rates from Influenza and Nontuberculous Respiratory Diseases Combined.

Massachusetts—For the Periods 1887-1892 and 1914-1919. Monthly Death Rate from Pneumonia.

Massachusetts—For the Periods 1887-1892 and 1914-1919. Monthly Death Rate from Bronchitis.

England and Wales—1847-1918. Annual Death Rate from Influenza.

England and Wales—1847-1918. Annual Death Rates from Influenza, Pneumonia, Bronchitis, and Influenza and Nontuberculous Respiratory Diseases Combined.

England and Wales—Epidemic Period of 1847-1848. Death Rates from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined.

England and Wales—Nonepidemic and Epidemic Periods, 1889-1892. Death Rates from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined, by Age.

England and Wales—Nonepidemic Period of 1896-1897. Death Rates from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined, by Age.

England and Wales—Nonepidemic and Epidemic Periods, 1896-1900. Death Rates from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined, by Age.

England and Wales—Epidemic Period of 1898-1900. Death Rates from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined, by Age.

London, England — Nonepidemic and Epidemic Periods, 1845-1848. Death Rates from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined, by Age.

London, England—Epidemic Period of 1847-1848. Quarterly Death Rates for Period of 1845-1852. from Influenza, Pneumonia, Bronchitis, Phthisis, Typhus Fever, Childbirth, and Influenza and Nontuberculous Respiratory Diseases Combined.

London, England—Epidemic Period of 1847-1848. Weekly Death Rates from Influenza, Bronchitis, Pneumonia, and Nontuberculous Respiratory Diseases combined.

London, England—Epidemic Period of 1890. Weekly Death Rates from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined.

London, England—Epidemic Period of 1891. Weekly Death Rates from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined.

London, England—Epidemic Period of 1891-1892. Weekly Death Rates from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined.

London, England—Epidemic Period of 1893-1894. Weekly Death Rates from Influenza, Bronchitis, Pneumonia, and Influenza and Nontuberculous Respiratory Diseases Combined.

The Feast of Flowers in Madrid.—For six years the custom has prevailed in Madrid of conducting a so-called Feast of Flowers for the exclusive benefit of the needy tuberculous. The proceeds this year were 160,000 pesetas, which shows a marked increase over previous years.—*El Siglo Médico.*

THE DARK FIELD ILLUMINATION METHOD IN EARLY DIAGNOSIS OF SYPHILIS.

By RALPH L. DOURMASHKIN, M.D.,

NEW YORK,

CAPTAIN, MEDICAL CORPS, UNITED STATES ARMY, HON. DISCH., FORMERLY CHIEF OF VENEREAL SERVICE, CAMP HOSP. NO. 29, A. E. F., FRANCE.

THE importance of laboratory findings as a means of positive diagnosis in certain pathological conditions is very well known to the general practitioner. We have grown so much accustomed to the idea of the absolute necessity of finding tubercle bacilli in the sputum before a given case may pass as that of pulmonary tuberculosis that probably very few would place reliance on physical signs and symptoms alone without having the patient's sputum thoroughly searched for the acid-fast organisms. That has been drilled into us time and time again. We examine as a matter of routine the sputum of every case presenting suspicious lung symptoms or signs. Various pathological secretions such as obtained from pleural or peritoneal cavities; also spinal fluids, urine, etc., etc., are conscientiously searched for tubercle bacilli by many as a matter of routine. The finding of *Bacillus diphtheriæ* in cultures taken from sore throats constitutes another familiar example, as well as the finding of *Bacillus typhosus* in the patient's excreta is regarded as absolute proof of the existence of the disease. We examine every case of urethral discharge for the Gram negative diplococci, and no case of intermittent chills and fever is passed without having the patient's blood thoroughly searched for the malarial parasites. In each of these instances the tendency is to arrive at the most accurate diagnosis by actually demonstrating the causative organisms microscopically.

Yet, how frequently do we diagnose the existence of one of the most widely spread diseased conditions coming daily under our observation, a condition in which the most accurate and the earliest diagnosis is of vital importance to the patient as well as to the community; how often do we diagnose the existence of syphilis by finding the causative organism of the disease, *Spirochæta pallida*, in the secretions taken from the various luetic lesions? The general practitioner, of course, knows of such a thing as the dark field vision method by which *Spirochæta pallida* can be demonstrated in syphilitic secretions, yet the interest which he takes in it is entirely academic. But few take the pains of utilizing the above method as means of diagnosticating syphilis. As a practical method, it may be stated, the dark field examination is unknown to the medical profession at large. A very large number of hospital laboratories, while doing every conceivable bacteriological or serological examination for diagnostic purposes, do not include the dark field work in their scope.

Thus the most accurate, yet the simplest method by which syphilis can be detected in its earliest stage, when the only manifestation of the disease is a small abrasion or an ulcerated papule, frequently passed as herpes, finds but a limited application. When it is considered how difficult it is to demonstrate tubercle bacilli in the early stages of pulmonary tuberculosis, and that the earliest stage of a no less important disease, syphilis, is *the* opportune time when the causative organisms may be found, one is at a loss to understand why this opportunity is not being utilized on a wide scale. Probably too much stress is being laid on the Wassermann complement fixation test as a means of diagnosis in syphilis, although all recent studies tend to show that the Wassermann reaction, while being of tremendous value is, nevertheless, not absolutely diagnostic of syphilis. The reaction is present in certain other conditions and is frequently absent in the primary stage, when a correct diagnosis presents more difficulties.

The Army requirements of exact laboratory findings in connection with the clinical diagnosis have placed the dark field work in the foremost ground, the place it rightly deserves. At no other time have the dark field examinations been used as widely and systematically as during this war in the Army hospitals and venereal clinics, both in this country and abroad. It has been the author's opportunity to study a large number of venereal sores while on duty with the American Expeditionary Forces in France. A dark field examination was made on every case without any reference to its clinical characteristics. The little effort which was required to demonstrate *Spirochæta pallida* in the venereal sores having the clinical characteristic of primary lesions was a most striking and impressive feature. The importance of the dark field examination was further emphasized in those cases of apparently innocent looking lesions which otherwise would have passed without attracting much attention, but which on examination proved to contain the *Spirochæta pallida* sometimes in large numbers. From the point of view of the Army probably no other microscopical procedure was of greater help. A malignant disease was rapidly and correctly spotted in its earliest stage, often in the very first day of its manifestation, the soldier was put on energetic antisyphilitic treatment immediately without waiting for the Wassermann reaction or the appearance of the secondary symptoms. With a positive dark field examination making the early administration of the antisyphilitic treatment possible, the Wassermann reaction becomes unnecessary, unless for checking purposes, at later dates.

Technique.—It cannot be too strongly emphasized that of all bacteriological examinations the dark field is one of the simplest. It is a more rapid procedure than that of examining sputum for tubercle bacilli which requires tedious staining, or examining for *B. diphtheriæ* or *B. typhosus* which requires culturing in each case. It should and ought to be done in the physician's office as a matter of routine in all cases of venereal sores or any suspicious open lesion, as a part of the time given to the patient, the latter waiting for his verdict.

A successful dark field examination depends upon three factors and it is the constant remembrance of these factors that constitutes the secret of the success, rendering any examination easy, speedy, and certain. These factors are: (1) Plenty of strong artificial light. (2) Plenty of immersion oil. (3) Plenty of moisture on the slide. Any deviation from the above conditions such as an insufficient amount of artificial light, or an in-

sufficient amount of immersion oil or of moisture on the slide, will either render the examination extremely difficult or result in the failure to find the organism. It must be remembered that the *Spirochæta pallida*, when seen under microscope, although a very distinct structure, shows no tendency to stand out too conspicuously and it takes all the three above mentioned factors to bring it out with the maximum effect.

A few words about the apparatus. It consists of an ordinary microscope from which the substage condensor is removed and a dark field illuminator attached instead. The substage may be retained and a superstage illuminator used with equally good results. What is known as a funnel stop is inserted in the oil immersion objective. Condensed artificial light must be used for the work and an adjustable microscope lamp with aspherical condensor will suit the purpose best as it gives the best corrected light. The arc light lamps, while giving a very powerful light, lack steadiness and will give, as a rule, much trouble.

The *Spirochæta pallida* ought to be demonstrated in the secretions taken from any open syphilitic lesion of whatever stage of the disease. At times they may be found in the serum obtained from the secondary rash lesions. They can be demonstrated in the secretion obtained from the inguinal glands, often in almost pure cultures. The gland secretion is obtained by inserting a hypodermic needle into the gland and massaging the latter for a few minutes. A few drops of the secretion may be thus obtained by aspiration. This diagnostic procedure is of extreme importance in cases where the lesion on the penis has just been healed, making a dark field examination impossible, but where the enlargement of the inguinal glands is still present.

Before an examination is undertaken it must be ascertained whether the patient has used antiseptic powders or ointments on his sore, which is very often the case. It is useless to make a dark field examination in such cases for the organisms will be killed by the treatment. The patient should be instructed to report five or six days later, meanwhile abstaining from any treatment.

The superficial secretion should be wiped off and a drop of serum should be gently squeezed out of the sore. The superficial serum should not be used for the following reasons: (1) The organisms are very frequently absent in the upper layer of the secretion, (2) The débris which is more abundant in the superficial secretion will decidedly hamper the proper examination for the spirochete. Whenever possible clear serum should be used. Admixture of blood or pus will float the microscopical field with numerous cells which will screen off the delicate structure of the spirochete, rendering its detection difficult. In mixed venereal sores with much purulent secretion the drop should be diluted with sterile saline solution. A drop of the secretion is caught in the center or the side of a cover glass which is then placed on a slide. Plenty of cedar oil should be placed on the top of the cover glass, *also on the dark field substage or superstage illuminator.* The latter use of the oil manifestly helps illumination. The illumination will not occur if the oil is omitted altogether. The examination should be performed in a darkened room but as much of the artificial light should be thrown on the field as possible. The diaphragm should be widely opened.

When the field is centered the silvery appearance of the illuminated organic structures, such as pus cells, an occasional red blood cell, etc., will stand out conspicuously in contrast with the background, which should be of an intense brown color. An absolutely black background indicates an insufficient amount of light and under such circumstances the *Spirochæta pallida*, however numerous, will not lend itself to detection, although such structures as pus cells may appear brilliantly illuminated in the same field. The presence of Brownian movements, numerous minute dancing specks in the field, indicates the presence of sufficient amount of light and moisture on the slide, and under such circumstances it is safe to proceed with the examination.

The Spirochætæ pallidæ, as a rule, are present in sufficient numbers to render their detection a speedy procedure. However, cases will present themselves often enough where a prolonged search is necessary before the organisms will be found. Especially is this true in cases of mixed venereal sores, in partially healed lesions, or in cases where antiseptics were used. It is for this reason that no slide should be discarded unless it has received a thorough search. The examination should be repeated at frequent intervals, if negative.

When found the *Spirochæta pallida* will appear as a silvery, very slender, highly flexible structure which is spirally wound, having anywhere from ten to twenty turns. Its unusual length immediately attracts one's attention, being frequently twice the diameter of a red blood cell. The turns throughout the length of the organism will appear to be closely set and of more or less equal size and shape. The organism will be seen to be slowly moving across the field, the movements being corkscrew-like—a very characteristic and diagnostic feature. The body as a whole may be straight or bent, especially at the ends, but the regular spiral turns are retained very well.

The *Spirochæta pallida* must be differentiated from other spirochetes of which *Spirochæta refringens* is the most important. The author has seen a number of venereal sores in which *Spirochæta refringens* was found in pure cultures. The clinical characteristic about those lesions is the profuse purulent discharge. The following table will differentiate the two organisms:

Spirochæta pallida.	*Spirochæta refringens.*
1. Body very slender.	1. Body much coarser.
2. Has from ten to twenty turns.	2. The turns are much fewer, anywhere from five to eight.
3. The turns are regular.	3. Extremely irregular.
4. Moves slowly.	4. Movements very rapid; may be compared to lightning. Difficult to follow it up as the organism flashes across the field.
5. Retains its turns.	5. Does not retain its turns.
6. Does not take up methylene blue.	6. Takes up the stain.

The dark field is by no means the only method by which the *Spirochæta pallida* may be detected. A number of special stains are employed for this

purpose but none of them is as nearly reliable as the dark field method. Slides in which spirochetes were demonstrated by the dark field method, in subsequent staining frequently proved to be negative. The India ink method is very commonly used and offers about the best substitute when the regular dark field apparatus is not available. A drop of India ink is mixed thoroughly with a drop of secretion taken from a lesion and is thinly and evenly spread over a slide like a blood smear preparation. It is then examined with an ordinary microscope, using an oil immersion objective.

The great drawback to all stained preparations lies in the fact that one is unable to study the movements of the organism. The author has suggested the use of a wet preparation made up of a minute drop of India ink placed on a slide and mixed with a drop of the secretion in question diluted with physiological saline solution. A cover glass is applied over the mixture before giving it a chance to dry. The moving *Spirochæta pallida* may frequently be seen by this method. The serious objection to it, as well as to any India ink method is that the ink may normally contain spirochetes which may be mistaken for the *Spirochæta pallida*.

Summary.—1. The dark field is the best and the easiest method in early diagnosis of syphilis.

2. It should be used as a matter of routine in all venereal sores or any suspicious open lesion.

3. Where the venereal sore is healed, an attempt should be made to examine the secretion obtained from the inguinal glands.

4. Antiseptic powders or ointments used on a sore render the examination useless.

5. Plenty of strong artificial light, plenty of immersion oil and plenty of moisture on the slide are the necessary factors insuring a speedy and successful dark field examination.

6. The *Spirochæta pallida* must be differentiated from *Spirochæta refringens* which is, as a rule, easy.

7. The stained preparations are not reliable.

53 St. Mark's Place.

DRUG ADDICTION CAUSES ACIDOSIS AND RESPONDS TO ALKALINE THERAPY.

By CHARLES A. ROSEWATER, M.D.,

NEWARK, N. J.,

CAPTAIN, MEDICAL RESERVE CORPS, U. S. ARMY.

"Acidosis," says Hawk, "may be considered as a condition brought about by the excessive withdrawal of bases through the formation of acids within the body." He further states, "Even in the most severe acidosis there is but slight alteration in the reaction of the blood, since the ability of the body to protect itself against the acid production is very remarkable. The normal reaction of the blood is slightly alkaline. If there be but slight deviation from the normal reaction, health rapidly departs and death may ensue."

Regardless of the underlying cause of drug habituation, it is evident that in drug addiction we are confronted by a condition of perverted metabolism, manifesting itself in symptoms of toxemia. A comparison of the symptoms presented by the drug addict, especially when deprived of his drug, with those noted in acidosis (such as in diabetes, particularly, impending coma) shows a striking similarity. A study of these symptoms has led the writer to institute an inquiry as to whether or not drug addiction causes acidosis, in the hope that the information would lead to the devising of some practical plan for relieving the sufferings of a most unfortunate class of individuals. In pursuing this study he has enjoyed the cooperation of Dr. Stephen P. Jewett, Psychiatrist to Bellevue Hospital; Dr. Otto Lowy, Serologist, Newark, N. J., and Lieut. W. D. Silkworth, late of the U. S. A. Neuropsychiatrical Hospital at Plattsburg. To these gentlemen he is profoundly grateful.

G. W. Crile, demonstrated that, when the H-ion concentration of the blood of an animal had been increased to the point of actual acidity of emotion, exertion, or anesthesia, and the animal was then deeply morphinized, the blood did not return to its normal alkalinity, that is, the body had lost its power to neutralize acidity. His clinic also confirmed the fact that heavy morphinization hinders or even inhibits the neutralization of the increased acidity caused by anesthesia.

The writer has failed to learn of any studies of the blood of drug addicts with reference to the subject of acidosis. The importance of such a study is apparent when it is appreciated that all the characteristic symptoms, both physical and mental, manifested by drug addicts, can be caused by acidosis.

To secure light upon this point the blood of five drug addicts was analyzed by Dr. Lowy, with the following result: Case I, 48.5 c.c. (per cent.) CO_2 combined with 100 c.c. plasma; Case II, 29.6 per cent. CO_2; Case III, 39.0 per cent. CO_2; Case IV, 40.9 per cent. CO_2; Case V, 48.5 per cent. CO_2. The blood of Case II was again examined, one week after the drug was discontinued, and showed 54.1 per cent.

According to Hawk, the alkali reserve in the normal resting adult is between 80 and 53 volume per cent., and it is a generally accepted fact that figures below 50 per cent. in adults indicate acidosis. As stated above, Hawk has emphasized the significance of even slight variations from the normal, and it would therefore appear that we are justified in concluding that acidosis is an important factor, if not the main factor in habituation phenomena. This view is further supported by the results of the treatment of the symptoms of drug addiction by alkaline therapy.

Oscar Jennings of Paris appears to have been the first to employ alkaline therapy in the treatment of chronic morphinism, and to attribute the symptoms to an "acid state," but he confined his attention to neutralizing the hyperacidity of the stomach. Some years later, Erlenmeyer, working along similar lines, claimed to have arrested or greatly modified all the withdrawal symptoms of morphinism by alkaline therapy. He also concentrated his attention upon the hyperacidity of the stomach. Evidently Jennings and Erlenmeyer were on the right track, but stopped short of the mark, for in the light of our studies it appears that alkaline therapy must be pushed to saturation and must be combined with thorough elimination, preferably by the method described by Pettey, whose "physiologically balanced purge" rests upon a scientific basis.

There is good reason for believing that drug addiction should be treated along lines similar to those advised by competent authorities in the treatment of diabetic coma; the treatment being, of course, modified to meet the requirements of the individual case. Along these lines, giving sodium bicarbonate intravenously in physiological salt solution, and by mouth in copious watery solutions, we supply the normal alkalizing agent, and also dilute the toxic agents and stimulate the heart and the kidneys. We employ the Pettey purge, and supply carbohydrates by glucose solution. With reference to diet, we follow the suggestion of Dr. Tom Williams of Washington, who, writing upon "Acidosis and the Brain," states: "In the diet there should preponderate carbohydrates for heat-forming purposes, and richly basic substances to antagonize the acid formed by the proteins. These are found in fruits containing citrates or malates, and in vegetables, which usually contain large amounts of alkalies."

We find that by the method outlined the accustomed drug can be withdrawn with remarkable facility and without subjecting the patient to the sufferings attendant upon practically every other plan of treatment. The plan is so far superior to the "hyoscine treatment" and other "knock-out treatments" and it is so easily employed, that the writer feels confident that, while it is in no sense a "cure all" or a panacea, it is scientifically sound, and, when intelligently applied, will mitigate the sufferings of a misunderstood and accordingly mistreated group of individuals.

The crying need for immediate relief for suffering drug addicts prompts the writer to publish this preliminary and necessarily incomplete report, in the hope of stimulating a searching inquiry into the blood, the cerebrospinal fluid, and the urine of drug addicts, and encouraging the rational treatment of these unfortunate members of society.

Cancerous Linitis.—According to Carnot, linitis of the stomach is a radiographic syndrome—esophageal retention; retracted stomach, which is also rigid and indispensable and pyloric incontinence. The term linitis as a special affection of the stomach (plastic linitis) is in reality an anatomo-pathologic condition due to several conditions, one being a continuous infiltration with cancer cells. In the author's case the fatal end came from perforative peritonitis.—*La Presse Médicale.*

Aberrant Wassermann.—A contributor to the *Journal de médecine et de chirurgie pratiques* for May 25 states that even the best technique may be vitiated by a faulty interpretation. Too great dependence on a negative reaction may result in vicious interpretation, and this is true of the entire course of the disease. Whatever the serodiagnosis, the Wassermann is not a safe guide to treatment, which must be pursued along the old lines —that is, the patient must get his three or four years of treatment, just as if no reaction had been taken; but the latter should, of course, be practised for statistical purposes. This doctrine is applicable only to the first years of the disease. In ancient syphilis diagnosis by the Wassermann may be the basis of treatment. To use the Wassermann on a syphilophobic as a means of convincing him of his freedom from the disease should not be tolerated, because of the possibility of swindling the patient. In regard to permitting marriage, Wassermann tests should be excluded and no marriage sanctioned until six years after infection and eighteen months after the latest symptoms. This is the general rule, but the period may be reduced to three years in certain cases kept at the start on intensive treatment with a series of negative reactions.

Medical and Surgical Lessons of the War.

TRENCH NEPHRITIS.

By JOHN RYLE, M.B. (Lond.), M.R.C.P.

LONDON, ENGLAND.

Introductory Note.—In spite of exhaustive researches conducted during the War with a view to determining the causative pathology of Trench Nephritis no conclusive theory has thus far been advanced. With the cessation of hostilities and the elimination of those factors with which the incidence of the disease appears to be associated it would seem that further opportunities for investigating the problem must now disappear.

Individual observation and organized research have established the condition as being wholly distinct from other known varities of nephritis and as possessed of very definite clinical and pathological characteristics of its own. It is probably not a new disease, for both in its etiological and epidemiological features the widespread nephritis of the American Civil War seems closely to have resembled the trench nephritis met with among allied and enemy forces during the period 1914-1918.

The main conclusions of the numerous British investigators—among whom should bee included Langdon Brown, Abercrombie, Dunn and McNee, Keith and Thompson, de Wesselow, Mclean and Wilson, Tytler and Ryle—are essentially similar. By some of these particular aspects of the disease were examined with elaborate care, and by them, as well as by other observers, the clinical picture and the morbid anatomy and histology have been very fully described.

Evidences in regard to causation, however, are still mainly negative, though recent suggestions by J. A. Wilson in regard to a filter-passing organism must not be overlooked. Extraneous chemical agents, such as the metallic poisons, exposure to wet and cold, the acute infectious diseases, and syphilis have been, so far as possible, excluded as causal agents; previous nephritis and albuminuria show little or no obvious association; no bacteria occurring in the throat and alimentary tract, and no organisms recoverable from the urine or blood in line or at autopsy have been definitely incriminated; blood taken from early cases and injected into guinea-pigs produced no disease. And yet in a careful review of epidemiological, clinical, and pathological features it is difficult to avoid the conclusion that the disease must be an infective one.

It is the aim of the present paper to chronicle certain observations relative to the epidemiology and early clinical findings, and by a correlation of these and other data to provide additional presumptive evidence for the infective theory.

Before proceeding with the main theme a summary is also given of certain pathological findings previously reported by Tytler and the author. The only peculiar value of these as compared with other observations lies in the fact that they were made in cases which died at a very early stage of the disease. In several instances death had taken place suddenly "in the field", while in the remainder death occurred in casualty clearing stations whither the

patients had been sent as soon as acute symptoms were manifest.

Pathological Summary.—In this early phase the most remarkable naked-eye changes were not, as might be supposed, to be found in the kidneys. The lungs and spleen showed far more obvious departures from the normal, and even suggested the possibility that the lung condition might be primary. Shaw Dunn on the strength of the histological changes had previously suggested the theory that the action of irritant gases might be a causal factor.

Briefly the pulmonary changes included extreme edema, closely similar to the edema found in cases of phosgene poisoning, and frequently associated with bronchitis or bronchopneumonia. This bronchial infection would appear to have been a secondary process; it was especially observed in the winter 1916-17 when catarrhal diseases and influenzal capillary bronchitis were widely spread among the troops. The alveoli were filled with serum and a considerable deposit of fibrin; leucocytes were commonly scattered through the lung tissues. Histologically the picture closely resembled lobar pneumonia in its early stages; thrombi were often to be seen in the small vessels.

The spleen was definitely enlarged in the majority of cases, sometimes to nearly twice the natural size; it was fairly firm on section but congested, and showed numerous small macroscopic hemorrhages. A similar condition, but without the hemorrhages, is not infrequently seen in pneumococcal infections. Polymorphonuclear leucocytes were present to an unusul degree throughout the spleen pulp.

The kidneys to the naked eye showed very slight changes. They were seldom enlarged or much engorged and never "blood-dripping." Occasionally the glomeruli stood out like glistening drops, as described by Shaw Dunn. Histologically the glomeruli were swollen and leucocytes were numerous; the tubular epithelium showed degenerative changes but these were rarely advanced. Fibrin thrombi were to be found in the smaller arterioles.

Subpleural, subepicardial, cerebral, and other small hemorrhages were occasionally recorded. The brain in several cases showed a moderate subarachnoid edema.

The observations in the ensuing sections are based on a clinical and numerical study of about 150 cases, which came under the direct care of the author during the early months of 1916 and the whole of the winter of 1916-1917. Cases were also admitted during the summer of 1916 but were few in number. It was during the winter period that correlative bacteriological and histological researches were conducted by Major Tytler, C.A.M.C., to whom the author is indebted for the pathological data noted in this section.

Etiology and Epidemiology.—The epidemic curve showed a definite seamonal elevation and excepting in the first year of the War this elevation always took place during the winter months. The following figures of the monthly admission rate to a Casualty Clearing Station receiving cases from a certain famous sector indicate roughly the rise and fall in the sick-rate attributable to the disease during the period Oct. 1, 1916-March 31, 1917. The Clearing Station was one of four, evacuating cases from five infantry divisions and other local troops, so that a multiplication by four of all the figures quoted hereafter will give a rough and probably a low estimate of the total figure for the district. A diagnosis of Trench Nephritis implied the presence of other stigmata than albuminuria alone. The curve of admissions is shown graphically in the accompanying chart as well as in the table.

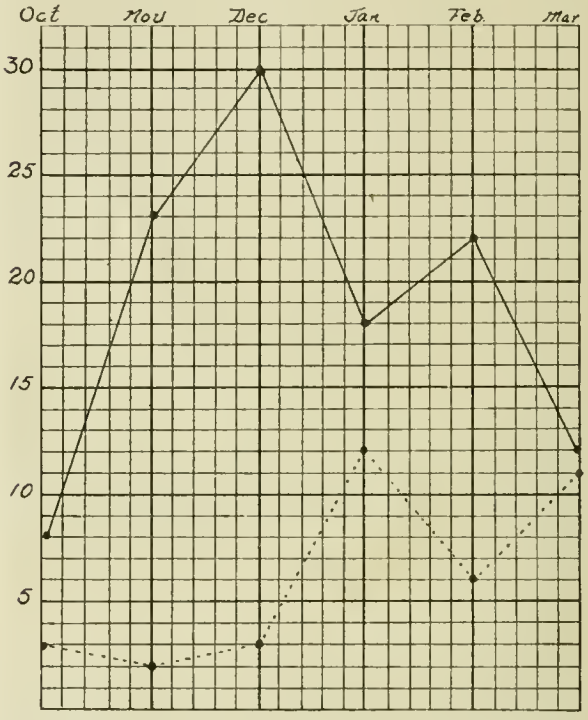

Chart showing monthly admission rate for nephritis and albuminurio to No. — C. C. S., from October 1, 1916, to March 31, 1917 (six months). The upper, continuous, line denotes the nephritis admissions, the dotted line the albuminuria.

Monthly Admission of Trench Nephritis to No. — C. C. S. from Oct. 1, 1916, to March 31, 1917.

October, 8;	December, 30;	February, 22;
November, 23;	January, 18;	March, 12.

The weather during this winter was typical Flanders weather; that is to say that it was almost continually wet and cold with intervals of hard, dry frost. The ages of the men fell within the limits of "military age", and neither youth nor advancing years appeared to give undue predisposition. More than two-thirds of the cases came from the five divisions referred to, and these divisions occupied the same positions during the period stated. The total number of cases admitted from them was 101. Of these 41 (or 40 per cent) came from a single division. The remaining four divisions provided 19, 18, 13, and 11 cases respectively.

Thus it would seem that in one division the liability to "infection" was much greater than in the other four, and actually twice as great as in the worst of these. The whole sector, but particularly that part occupied by the division with the high incidence, provided, it is believed, a disproportionately large number of cases as compared with the rest of the British front.

During the same period 8 cases were admitted from units coming under the descriptions of Corps

Troops. The majority of these would in all probability have been working under better conditions than the front-line troops. Cases were also reported among hospital orderlies so that actual trench-life would not appear to have been an essential factor.

Instances of several cases being admitted from the same unit were numerous, and occasionally two or three men were admitted in the same day from a single battalion. During the period under review:

7	cases	were	admitted	from	one	unit	once
6	"	"	"	"	"	"	"
5	"	"	"	"	"	"	"
4	"	"	"	"	"	"	4 times
2	"	"	"	"	"	"	15 times

Throughout the War cases among officers were proportionately rare.

In this distribution according to formations and locality and in the comparative infrequency of cases among officers the epidemic showed a closely similar behavior to other war-diseases of known infective origin. Spirochætosis Icterohæmorrhagica for instance which occurred in epidemic form in 1916 was confined roughly to the same sector as that under discussion, and particularly to certain trenches in that sector. It showed a closely analogous unit-incidence and only one doubtful case in an officer was reported. As is now well known this spirochaetal infection was traced to the field-rat.

In its first appearance and in its almost simultaneous rise to epidemic form during the summer of 1915; in its wide distribution along the whole front and its persistence throughout the whole War; in its affection alike of forward-area and back-area troops; perhaps also in its greater prevalence in certain divisions and at certain times, the nephritis epidemic showed a still closer similarity to trench fever—a lous-borne disease.

The impression gained at the time of the investigation, though not based on ascertained figures, was that the heavily affected division showed a bad bill of health in other respects also. This might have been attributable (1) to the bad local conditions to which the men were exposed; (2) to overcrowding in billets; (3) to a comparatively inferior organization and morale, or (4) to a combination of these factors with their attendant "lousiness" and liability to infections. It is a well recognized fact that directly or indirectly pediculosis and scabies were responsible for an exceedingly high proportion of the total sick-wastage.

"Lousiness" is a factor common to all armies in the field, perhaps almost the most common factor. Langdon Brown, in a comparative discussion of nephritis in the American Civil War and the present War, indicated the stationary nature of the fighting as the principal common etiological factor. In all probability at least an equal claim might be made for pediculosis.

No direct association of trench nephritis and trench fever is urged, but it is not unreasonable to suggest, on the foregoing hypothesis, that the former as well as the latter may have been carried by the louse.

If the louse *was* the intermediary in trench nephritis the winter rise in the incidence is susceptible of explanation in that overcrowding in billets, less frequent washing, a much lessened frequency in individual louse-hunts, and the wearing of thick woolen undervests and pants were simultaneous phenomena in every way calculated to encourage pediculosis. Pediculosis and scabies are generally supposed to attain their maximum in the civil community during the winter months for similar reasons. Trench fever was to such an extent pandemic and permanent that its monthly fluctuations did not attract particular attention, but it is conceivable or even probable that it showed a winter elevation akin to that shown by the nephritis. Unfortunately figures are not available for comparison. During the period under review there were admitted to the same Clearing Station 38 cases of albuminuria without other signs of nephritis. In spite of the fact that in the division with the second highest incidence of nephritis a special search for cases of albuminuria was being conducted, the monthly admission-rate to hospital was found to be in inverse ration to the admission-rate for nephritis. The conclusion to be drawn from this, if any were warrantable with such meagre figures, are not very apparent.

On a superficial study of the epidemiology there is, to recapitulate, reason to presume that the disease was infective and a distinct possibility that it may have been yet another of the louse-borne maladies.

Should the claims of Wilson and his collaborators that both trench fever and trench nephritis are due to filter-passing organisms find confirmation, the suggestions and method of inquiry outlined above and based on a rough comparative epidemiology may perhaps be considered justifiable. In typhus also, another louse-borne infection, a filter-passing organism awaits further investigation.

The Clinical Features of Trench Nephritis in its Initial Stages.—The general description of a case of moderate severity may be briefly given as follows. With a history varying from two days to three weeks but more frequently of seven to fourteen days' duration, and a complaint during that period of a vague unfitness, headaches, cough, shortness of breath on exertion, and occasionally of difficulty in adjusting the equipment of lacing the boots, the patient was admitted to the Clearing Station with more urgent symptoms of sudden development. Pallor, anasarca, and dyspnea were the outstanding features and the urine, though often almost normal in quantity, contained albumin in large amount, in some cases solidifying completely on heating. The dyspnea was usually the worst symptom and was often an objective manifestation even during rest in bed. Rapid improvement was the rule, unless there was an associated infection of the bronchioles. In this event grave symptoms and death due to an extreme degree of pulmonary edema were not uncommon. In a small group—only one case in this series—there were absence of superficial edema, diminution or suppression of urine, and uremic manifestations. It was in cases of this kind that the sudden deaths in billets occurred, and the diagnosis was only made postmortem. All grades of severity were seen, and it was usual to evacuate cases to the base as soon as objective dyspnea and prominent anasarca had abated.

Routine examination revealed the following features:

1. Pyrexia: In further support of the infective theory, fever, or a history of fever, was naturally sought for, but without much success. It is conceivable that in a disease so insidious in its onset a mild pyrexia may have accompanied the actual inception, but cases admitted for obscure pyrexia did not develop nephritis while under observation in the Clearing Station, though it is possible that some may have done so later.

In a few cases a transient pyrexia, from 100 to 103 was present, but nearly always there was a concomitant bronchitis. In one pyrexial case with no evidence of bronchitis an organism closely resembling the pneumococcus was obtained on hemoculture, but the result was never reproduced.

2. General Appearance: The face was pale and puffy and the eyelids especially were edematous. The feet were swollen and pitted on pressure, and there was anasarca of all dependent tissues. Thus after a short sojourn in bed the back and loins showed deep creases corresponding with the folds in the bed-clothes. Cyanosis of lips and ears was present in the worst cases.

3. Alimentary System: The tongue was clean or lightly furred, and moist. Constipation was the rule. The abdomen was full and tense, apparently on account of the tissue-edema and retroperitoneal infiltration. Vomiting was occasionally recorded.

4. Circulatory System: There was early evidence of a moderate increase in blood-pressure. A high tension pulse, a loud aortic second sound, and sphygmomanometer readings of 140 to 155, with an average of 145 mm. of mercury, was found on admission in a small series of cases seen early in 1916. In this series the average length of history was 9.7 days. There was no evidence of organic cardiac disease, nor was pericardial effusion ever diagnosed.

5. Respiratory System: Symptoms referable to the lungs or bronchi or both were almost constant. Cough and dyspnea on exertion or even during rest were the most frequent complaints. In the severer cases, which are estimated as having composed about 25 per cent of the total, there was often obvious or even distressing dyspnea while the patient lay at rest in bed. Orthopnea was also observed, and continuous administration of oxygen was sometimes necessary. On account of these urgent pulmonary signs patients were sent in from time to time with a diagnosis of pneumonia or acute bronchitis. The actual cause of the dyspnea appeared to be pulmonary edema, of which there was ample confirmation in the cases which came to autopsy. The physical signs indicative of the condition were impaired resonance at the bases, an increasingly feeble entry from the angle of the scapula downward to the lower basal limits, moist sounds, and associated with these, expectoration of frothy serous fluid. As a terminal event the froth was poured or spluttered forth from mouth and nares in great quantity.

Bronchitis with sibilant rhonchi and an addition of a mucopurulent element to the sputum were commonly present, and seemed to contribute largely to the rapid failure in the cases which ended fatally. In a small number of these Pfeiffer's bacillus was isolated from the sputum. In cases of less gravity the sputum was small in amount or absent, even in the presence of cough and diminished air entry at the bases.

In a few cases the alveolar air was analyzed by Capt. Adrian Stokes, R. A. M. C. The carbon dioxide showed a normal percentage so that acidosis was not regarded as a factor responsible for the dyspnea. Possibly in the uremic type of case other results might have been found.

In the gravest cases a grey-white pallor with cyanosis of the lips and ears accompanied the other signs. In one case there was a large bilateral pleural effusion.

The involvement of the respiratory apparatus is thus seen to be a very striking feature of the disease, clinically as well as pathologically, in the early stages. It has not perhaps received sufficient emphasis in the literature generally.

6. Excretory System: The urine, as has been mentioned, was commonly not greatly diminished in amount. It was rare, except in the early uremic type, for the daily output to be less than 20 oz. and 40 and 50 oz. were commonly recorded. The average output for 24 hours in 7 cases was 45 oz. In one case with much anasarca and 5 parts per 1000 of albumin, 70 oz. (=2,200 c. c.) were passed in 24 hours. To naked-eye inspection the urine was not grossly abnormal. Macroscopic hematuria and "smoky" urine were exceedingly rare, though a small deposit was sometimes visible on settling, and the centrifugalized deposit contained red cells, leucocytes, and numerous tube-casts. The amount of albumin showed wide variations, but was roughly proportional to the severity of the symptoms. Occasionally it diseappeared within two or three days of admission of the case to hospital. In a series of 10 cases the amount varied from 0.1 to 2.5 per cent, with an average of 1 per cent as estimated by Esbach's method. The specific gravity varied between 1010 and 1018.

7. Nervous System: Unconsciousness coming on suddenly, often apparently during sleep, was the most striking feature in the uremic cases. In one case headache, confused mental state, and restiveness, suggesting an early "folie brightique", were observed. The cerebrospinal fluid in these cases appeared to be under increased pressure, presumably on account of cerebral edema and 20 c. c. could be withdrawn without difficulty.

Headache was a frequent symptom in the early history of many cases of the respiratory type.

8. The Spleen and Lymphatics: The spleen though found enlarged at autopsy was never palpable during life; the full abdomen and infiltrated tissues would have been a sufficient obstacle even with greater degrees of enlargement. The superficial lymph glands were never found to be enlarged unduly.

9. The Blood: The leucocytes in a small series of cases were between 8,000 and 10,000 per cubic millimeter. In 9 cases the blood-urea was estimated by Capt. Stokes. The readings varied from 0.04 to 0.15 per cent with an average of 0.07 per cent. Apart from headache, uremic symptoms were present in none of these.

10. Mortality and Prognosis: The mortality in the Clearing Station for the winter 1916-1917 was 4 per cent, but during that period several cases were brought in dead. No records are available of

deaths occurring later in the chronic stages of the disease after evacuation to the base or to England.

So far as could be determined the deaths occurred in the second week of the disease. In the 1916-17 series death was due to respiratory failure in every case. In one case seen in the spring of 1916, uremic symptoms were followed by a slight but definite improvement and then by death from respiratory failure.

In the absence of bronchitis the immediate prognosis may be said to have been good.

4. Conclusions.—A correlation of epidemiological, pathological, and clinical evidence would seem strongly to indicate an infective origin for the disease.

The epidemiological arguments have been already stated so far as the meagre figures available from the notes of an isolated observer will allow. The post-mortem findings as well as the clinical features both point to a possible respiratory origin for the disease, but the simultaneous involvement of lungs, spleen, and kidneys, and particularly the splenic enlargement and hemorrhages, favor a general blood-infection. On the analogy of pneumococcal lobar pneumonia there is no especial reason why localized changes in the lungs should indicate these organs as the primary focus.

The hypothesis of a blood-infection owing its origin to the bite of the louse is not therefore necessarily vitiated. In the liability to secondary infections of the bronchioles the disease followed the behavior of other systemic diseases, such as influenza, though doubtlessly the waterlogged condition of the lung tissue favored the implantation of organisms.

There was nothing to suggest an actual interrelationship between trench nephritis and trench fever, though certain "lower tract" cases, with hematuria, pain, and frequency of micturition, but no nephritic symptoms, were observed with similar "spikes" of pyrexia and shin pains akin to those associated with trench fever.

The absence of fever or a history of fever is perhaps the strongest argument against the infective theory, but it should be remembered that in certain other acute infective diseases, such as anterior poliomyelitis, the period of pyrexial invasion is so inconspicuous as frequently to escape detection, and yet the end-result changes are sufficiently grave and obvious. In trench fever also the initial pyrexial bout is often insignificant though the limb-pains and debility may be of long duration. The first of these is due to a filter-passer, and the second also is under suspicion of being due to a similar organism.

Pending confirmation of the work of Rose Bradford, Wilson, and Bashford on the filter-passers we must remain without definite conclusions. It is however hoped that the foregoing attempt to analyze and correlate other available data than those obtained by laboratory research may be not wholly devoid of value.

Special thanks are due to Major W. H. Tytler, C. A. M. C. and to Capt. Adrian Stokes, D. S. O., R. A. M. C., who were responsible for the laboratory investigations, and without whose help the observations briefly reviewed in this paper could not have been accumulated.

Medicolegal Notes.

Results from Physical Injuries.—The Indiana Appellate Court holds that the fact that an applicant for compensation under the Workmen's Compensation Act was suffering from a mental or nervous condition resulting from a physical injury, rather than from the physical injury itself, cannot have the effect of relieving the employer from liability. That court is committed to the doctrine that a "personal injury," as that term is used in the act, has reference not merely to some break in some part of the body, or some wound thereon or the like, but also to the consequence or disability that results therefrom. The court says that as it is apparent that certain mental and nervous conditions may be as effective in producing disability as a physical wound or the loss of a member, such conditions afford a basis for compensation. Of course a mental attitude toward an original injury voluntarily assumed cannot be said to be the result of such injury. Intentional and wilful practices and the use of mental processes by which mental and physical infirmities are developed into injurious conditions, will defeat a claim for compensation, as under such circumstances the injured employee becomes the responsible agent for his own condition.—Kingan & Co. v. Ossam (Ind.), 121 N. E. 289.

Explanation of X-ray Photographs by Experts.—In an action for personal injuries both the plaintiff and the defendant introduced witnesses, who had taken *x*-ray photographs of portions of the plaintiff's person, and the photographs were received in evidence. Complaint was made, on appeal, that the trial court erred in not refusing to allow doctors called by the defendant to testify as to what appeared in the skiagraphs. The defendant's three doctors on this subject testified at great length in regard to the *x*-ray photographs.

An illustrative question asked by the defendant of its witnesses was: "State whether or not, Doctor, Exhibit B does or does not show a curvature of the spine, as appears in the negative?" Objection to this question was sustained. The defendant cited a number of cases to the proposition that *x*-ray negatives and photographs, properly verified, are admissible in evidence; and this proposition was not disputed by the plaintiff. Cases were also cited by the defendant, holding that it is proper for experts to interpret and explain *x*-ray plates to the jury. They claimed, too, that some of the cases hold that a witness may testify as to what the photograph shows. The court thought the questions asked in the present case were within the ruling of Elzig v. Bales, 135 Iowa, 208-211, 112 N. W. 540, where it was said: "As demonstrative evidence, they serve to explain or illustrate and apply the testimony, and are aids to the jury in comprehending the question in dispute. No argument is required to show that when taken for either purpose they are the best evidence of what appears on them. The rule exacting the best evidence applies to the testimony of experts, as well as to that of other witnesses, and we are of the opinion that the court erred in permitting the doctor to testify to what appeared in the skiagraph."—Lang v. Marshalltown Light, Power & Ry. Co., Iowa Supreme Court, 170 N. W. 463.

Construction of Harrison Narcotic Act.—The Circuit Court of Appeals, Fifth Circuit, holds that Section 2 of the Harrison Narcotic Act, declaring that it shall be unlawful for any person to sell named narcotic drugs, except on a written order of the person to whom the drug is sold, applies not only to registered dealers, but to all sellers, for revenue is raised from the sale of prohibited drugs. Section 1 of the act punishes sales by persons who have neither registered nor paid the tax. Section 2 punishes persons who sell, not in pursuance of a written order of the person to whom the sale is made. The language of Section 2 is general, and does not restrict the prohibition to registered dealers in terms. Taking the law in its entirety, no person, whether registered or unregistered, can lawfully sell the prohibited drugs, "except in pursuance of a written order of the person to whom such article is sold," and an indictment which charged even an unregistered person with selling, not in pursuance of such a written order, would charge him with a sale prohibited by the act.—Pyke v. United States, 254 Fed. 225.

MORTALITY STATISTICS.

PRELIMINARY to any serious and sustained effort along public health lines, it is necessary to ascertain which conditions most seriously threaten the health of the community and also to determine whether the threat is of such a nature as to permit of an effective defense. Furthermore, it is essential to evaluate the effects of public health endeavor by a determination of the changes in the death rate from year to year. There are many other reasons which make mortality statistics interesting and instructive. But statistics generally are looked upon more or less with suspicion, and perhaps justly so, for they are susceptible of manipulation in various ways, all of which may assist in a falsification of the conclusions drawn therefrom. Mortality statistics which have been issued by the Government have been drawn from the so-called Registration Area and therefore present that situation as it exists in only a portion of the country, representative, no doubt, but still incomplete.

But we now have available the experience of the industrial department of a great insurance company, extending over a period of six years and involving over 635,000 deaths.* The geographical area covered by this volume is greater than that of the Registration Area and may be considered truly representative of the entire wage-earning population of the United States and Canada. Moreover, the figures are given in such form that their true relation to the entire number of persons is shown and in each instance the rate is carefully estimated. While it would be a hopeless task to attempt to summarize here the results of the work, it may be instructive to pick out for emphasis a few of the outstanding features that present themselves.

The death rate from tuberculosis has been steadily diminishing so that in the past six years the saving is great and more than justifies the amount of effort and money that has been expended to bring it about. Pneumonia, as was to be expected, has shown practically no change. The accidental death rate remains higher than in other countries, though it has lessened slightly in the past six years. Much of this loss is preventable in one way or another and represents the price the country pays for carelessness and indifference. The cancer rate has remained practically stationary in spite of the many alarms to the contrary. Scarlet fever and diphtheria both show a gratifying decrease during the period included, though the latter still causes over two per cent. of all the deaths. It is difficult to explain the stationary death rate shown in the diseases incidental to the maternal state. Whether one looks to the infections or eclampsia or hemorrhage, the diminution in the death rate is very small. Typhoid fever, on the other hand, has been reduced to less than one-half of its former mortality, a striking example of what concerted public action will accomplish. It will be interesting to see what the typhoid rate will be during the next two years. The vaccination of more than three million men and women during the period of the war is bound to have a definite effect upon the incidence of this disease throughout the country. The whole death rate, including all causes and all persons, was diminished by about eleven per cent. during the six years, surely a gratifying showing. As was to be expected, the rate in nearly all divisions is higher among the colored than among the white.

Such a collection of figures as is presented in this report hides a mine of information of the very highest value. It may be objected that insurance company statistics are not a just representation of the population because they are selected to a certain extent. Even in industrial insurance some selection occurs, but what may be lost in this way must be more than made up by the advantage of having all submitted causes of death passed upon by one central authority. The mechanism of State government has some disadvantages, not the least of which is its effect upon the medical registration and the collection of vital and public health statistics. It is to be hoped that this book represents the first of a series of similar publications which will appear at not too great intervals.

*"Mortality Statistics of Insured Wage-Earners and Their Families." Experience of the Metropolitan Life Insurance Company Industrial Department, 1911 to 1916, in the United States and Canada, by Louis I. Dublin, Ph.D., Statistician, with the Collaboration of Edwin W. Kopf and George H. Van Buren, New York: Metropolitan Life Insurance Company, 1919.

HERPES GESTATIONIS.

THREE theories have been put forward for explaining the pathogenesis of herpes gestationis, or autotoxic dermatosis of gravidism, as Pinard would have it. These are the microbic, nervous, and autotoxic theories. The microbic theory is no longer tenable, but the nervous theory is rather seductive, inasmuch as it recalls the pathogenic theory of zona. In a fairly large percentage of women who have been afflicted with a dermatosis during pregnancy, it has been noted that they were nervously irritable and in some cases the attack of the eruption has followed a severe emotion.

A violent pruritus occurring before and persisting with the eruption has been made a serious argu-

ment by the partisans of the nervous pathogenesis of herpes gestationis, and Sauvage has pointed out that herpes and the pruritus of pregnancy are merely different manifestations of a saturation of the nervous system by toxins abnormally manufactured during the gravid state. Given the evident symmetry of the cutaneous lesions, it is difficult not to suspect the part that the nervous system might play in this affection, but nevertheless the autotoxic theory appears to be more exactly applicable to both chemical and clinical facts.

During the eruption the daily output of urine is usually diminished, while it is not uncommon to observe a polyuria immediately following delivery. The urine is dark, slightly acid, while the principal solids—excepting uric acid, which is increased—are diminished in quantity, but after labor they increase. It has also been shown that the urine of these patients is hypotoxic, that during the eruption one hundred and fifty cubic centimeters of urine per kilogram of animal are required to kill a rabbit, while at the end of the eruption fifty cubic centimeters will accomplish the same result. In the patient's antecedents one will frequently discover other toxic dermatoses, such as urticaria, and instances have been recorded where the ingestion of certain foods has resulted in the production of a polymorphous eruption. A detoxication treatment is generally positive in results. Therefore it would seem logical to conclude that herpes gestationis is the result of a toxemia, while admitting that the intensity of the process may be exaggerated in nervously predisposed individuals.

A typical eruption occurring in a pregnant woman can leave no doubt as to the diagnosis; the good state of the general health, the pruritus, and the eruption are pathognomonic, but in some instances a differential diagnosis must be made with pemphigoid affections. In pemphigus acutus, pruritus is slight, the general condition serious, and death is the usual outcome. Pemphigus vulgaris is readily distinguished by its primary localization on the buccal and nasal mucosæ; ulcerations and papillomatous growths occur and cachexia rapidly ensues. When erythematous patches surmounted by very small vesicles are found, a diagnosis of eczema might be made, but there would be little pruritus and considerable secretion. Lastly, in polymorphous erythema the eruption is not symmetrical, the mucosæ are usually involved, the temperature is raised, and there is a marked albuminuria.

PALMAR AND PLANTAR PSORIASIS.

GENERALLY speaking, psoriasis respects not only the palmar and plantar surfaces, but the entire hand and foot as well. In many cases an imaginary line, one above the malleoli, another above the radiocarpal joint, limits the lesions from downward progress. In the so-called inverted psoriasis, the conditions are changed; the feet and hands may be the seat of the cutaneous process without any lesions on the rest of the skin surface, or they may be the principal site of an otherwise mild psoriatic process. Palmar psoriasis is rarely strictly localized to the palm of the hand; it nearly always extends to the dorsal aspect of the fingers and hand, likewise to the wrist, especially on its anterior aspect, where the psoriatic character of the affection becomes more distinct. The nails usually offer some changes, such as small red puncta or striæ. The lesions begin in the form of dark red spots arising from the depth to the surface, then the epidermis dries and cracks. By coalescence these spots form plates with distinct arciform borders, but the epidermis is not thickened. The lesion appears to extend by its convex border in order to reach the dorsal surface. When the entire palm has become involved—which is frequent—the skin will be found to be glistening, not thickened, and presenting a peculiar cherry-red tint, quite unlike the usual psoriatic red; it is covered with fine, adherent squamæ. The folds of the skin are more distinctly marked, but fissures are generally absent.

The lesions are similar on the plantar surface of the feet, but sometimes a dry, parchment-like epidemic crust is present and the lesions usually attain the dorsal aspect of the foot. The lesions are more prone to arise on those parts where the pressure is greatest, although fissures are absent, the lesions are frequently painful, enough so to make walking difficult or even impossible. The affection is long in duration and obstinate to treatment.

The diagnosis is sometimes difficult when lesions on other parts of the body are wanting. Dyshidrosis, lichen planus, dermatitis artefacta or venenata, and trichophytosis may offer much likeness to palmar and plantar psoriasis. However, these affections are usually easy to distinguish, but the same cannot be said of keratodermia, eczema, and, above all, the syphilides. The secondary palmar and plantar syphilides are so essentially characteristic that they would give no trouble in the diagnosis, but this does not apply to tertiary lesions. Tertiary syphilides on the palmar and plantar surface are usually unilateral; they have a darker copper-colored tint, but may be a bright red in some cases. There is a notable infiltration of the dermis, while the borders of the lesions form circles or segments of circles and are thick and often fissured. The dorsal aspect of the feet and hands, likewise the wrists, are usually uninvolved, and changes in the nails are rare. Where doubt exists, the Wassermann reaction or antisyphilitic treatment will solve the question.

THE PROTEIN CONTENT OF DIET.

PROTEIN food does not occupy the high position in diet which was formerly the case, and this is especially true with regard to the protein of meat. There is published in the *American Journal of Public Health* for June, 1919, an article by Lieut.-Col. John M. Murlin, Sanitary Corps, U. S. Army, and Major Caspar W. Miller, M. C., U. S. Army,

detailing the preliminary results of nutritional surveys in the United States Army Camps. In this article it is pointed out that it is the general consensus of opinion amongst experts in nutrition that an excess of protein is undesirable in the dietary of a hard working man, since muscular work does not involve destruction of muscular tissue beyond the amount sustained by that tissue in muscular rest. The amount of protein, which in general is held to be sufficient to repair all the wastes of the body and to supply an adequate reserve, is 13 per cent of the total energy intake. It seems to be a matter of indifference to the muscles whether they receive their energy from carbohydrate or from fat, except that carbohydrate yields its energy more rapidly than does fat. Hard muscular work, therefore, can be done on a high carbohydrate diet or upon a high fat diet. It is of general experience, however, the authors state, that muscular work is done with less effort if there is a plentiful supply of carbohydrate. Moreover, it is well known that carbohydrate is a cheaper source of muscular energy than fat.

The conclusion has been come to by these investigators that all the requirements for the training of soldiers, that is, for men in the prime of life doing hard manual work, will be met by a dietary supplying 12½ per cent. of the total energy in the form of protein, 25 per cent. in the form of fat, and 62½ per cent. in the form of carbohydrate.

Views on dietetics have altered very considerably within the past few years. It is not very long ago that it was an article of faith that those who used a great deal of muscular energy required large quantities of protein in the form of meat, although it had long been observed that Italians and other Southern people did hard manual labor on a largely vegetable and fat diet and that the Japanese performed strenuous work mainly on rice. Now meat and protein food generally appear to be relegated to their proper place in the nutritional scale.

The Psychic Element in Pertussis.

Following the trend of the present day to note a marked psychic component in conditions which affect a large number of subjects at the same time, and in the absence of efficient exogenous causal factors, we are not surprised to see this inference operative in pertussis. It has been invoked to account for influenza through imitation, panic, fear, etc., just as it was in past centuries to account for the black plague. Whooping cough refuses to yield to rational remedies until toward its spontaneous termination, when any remedy which chances to be given gets the credit for cure. It is possible that when the disease has nearly run its course psychic factors can prevail over it, and this may be the mechanism of gashouse cures, automobile cures, and other more or less freakish remedies. Freakish is not used in the sense of irrational, for the remedies may be physiologically sound, but the same courses are without advantage in the onset and acme of the disease. Cozzolino, in *La Pediatria* for last March, does not recognize a psychic factor because pertussis attacks very young infants in full force, and is contagious in its early stage and not absolutely after the whoop has developed. If it were psychogenic its contagion would be in evidence through the entire presence of the whoop. Children would begin to whoop when they heard others whoop, but any layman knows that this is not the case. If it were suggestible, adults would also develop the whoop; yet in the adult this behavior is of the rarest. It has been shown that contagion in the bacillary sense ceases at or perhaps long before the thirtieth day of the disease. Allowing two weeks before the whoop develops, this would leave two weeks or so more of contagiosity, yet the whoop continues in the vicinity of another month. Moreover, we have as objective phenomena of pertussis, in addition to the constant presence of the Bordet-Gengou bacillus, a lympholeucocytosis, an increased density of the urine and increase of uric acid, a light hematuria, etc. In pertussis, carriers are unknown. The disease is believed to be contracted only from a victim. That a nervous component does exist has been shown by the sudden cessation of the whoops after amygdalotomy and vaccination. Direct suggestion does not seem to be efficacious.

Surgery of Gastric and Duodenal Ulcer in Continental Europe.

Before the great war the Britons, Mayo Robson and Moynihan, and the Americans, the Mayos, seem to have been regarded as teachers of the Continent in this province, especially in regard to duodenal ulcer. The *Correspondenz-Blatt für Schweizer Aerzte* for May 17 is devoted very largely to this subject in connection with the annual session (1918) of the Swiss Surgical Society. Kummer and Bircher, two of the leading gastric surgeons of the Continent, have each contributed a compendious article on the subject. While the above named Americans and Britons receive due appreciation in the introductory section, it seems to us that otherwise the Anglo-Saxons are made to take a back seat. The representatives of this race certainly comprise numerous surgeons aside from those properly honored. But the Finneys and Deavers and other heavy operators seem ignored in the Swiss papers, while Continental surgeons of whatever eminence are duly mentioned. It is true that many of the Continental surgeons of the Billroth type were pioneers not to be confounded with men of the present age. During the war the dearth of papers in Europe has led to the republication of hundreds of American and British articles on surgery in Continental journals, so that there is no ignorance of what is taken place in the Anglo-Saxon world, but rather the contrary. A few well-known French surgeons like Hartmann and Tuffier are given credit for their work. On the whole, however, the great preponderance of Teutons in the names quoted and in the reference lists causes us to ask if some form of propaganda is not being enacted in these Swiss articles. The mention of men of other races is more or less perfunctory, and even if Anglo-Saxons have done pioneer work in this field they seem to receive no credit for erecting a superstructure on that foundation. Today propaganda is to be recognized under every disguise.

News of the Week.

New York Association for Medical Education.—Some time ago we announced the inception of a movement to make New York a great medical center and noted the formation of an association for this purpose, with its list of officers. The association has now issued a statement of its organization and aims. In this it is stated that the proposal of a group of physicians, surgeons, and medical teachers of New York City to establish a central clearing house for medical education has so favorably impressed their colleagues that what has been for years past a dream and a hope has now become an accomplished fact. The medical profession has developed within itself an active organization to stimulate, obtain support for, and expand medical education for students and graduates of medicine in the interest of and ultimate better service to the public. The Association for Medical Education is now organized to offer opportunity to teachers and workers in the medical sciences, whether they be practitioners of medicine or wholly engaged in teaching and research, to participate in the consideration and direction of all matters affecting medical education. It also offers a medium through which the unsurpassed clinical material and research facilities of this metropolitan area may be made readily and conveniently available to all students and graduates of medicine from our own or other countries. The development and special encouragement of teachers of medicine will be one of the important functions of this association. It is felt by the incorporators that the City of New York is under obligation to assemble and provide resources for the teaching of medicine, in its broadest terms.

No one medical school or group of special interests, hospitals, laboratories, or individuals can command sufficient support to assume the representation or direction of an undertaking in which the entire profession and the public have so large a stake. The spontaneous and immediate support given to the Association's plans by the medical profession of New York City is a guarantee of the representative and democratic character of the undertaking. To accomplish the purposes of the Association, a corporate membership of three hundred active workers in the practice and teaching of medical sciences was selected and from this body a Board of Trustees, twenty-seven in number, has been duly elected. General members from the profession at large are provided for in the Constitution, and will soon be requested to take an active share in the deliberations of the Association. Among the incorporators are many who are not at present engaged in teaching, as well as members of the faculties of medical schools and of the attending staffs of both private and public hospitals. A Finance Committee has already obtained, within the profession, sufficient funds to provide for the immediate establishment and permanent maintenance of a Bureau of Information and Correspondence at the New York Academy of Medicine, No. 17 West Forty-third Street. Reliable data concerning all the facilities which are now, or can be made available for teaching purposes, will be assembled here; and from this office information concerning the details of courses, dates, fees, qualifications demanded, attendance requirements, etc., will be issued by bulletins and letters. This activity of the Association for Medical Education will be supplementary to the excellent work already well established, and which has been of such great value, by the Bureau of Clinical Information of the Society for the Advancement of Clinical Study.

A Committee on Education has been selected and is now organized, whose duty it will be to prepare plans and standards that shall insure a permanent improvement in the character of medical teaching in New York City; to keep informed concerning, and to pass upon the qualifications of teachers and the character of the courses they offer to graduate students of medicine; and to observe and regulate the manner in which engagements are met by those offering courses under the auspices of the Association. In order that the work outlined by the Association shall receive active and sustained consideration, Dr. Henry O. Reik of Baltimore, has been engaged as Executive Secretary to devote his entire time to the development of the project.

The active cooperation of the Public Health Committee of the Academy of Medicine was offered to the Association, and a study of the dispensary and hospital teaching facilities of the city has been undertaken by its permanent staff.

What has been a gain to one school or hospital has often heretofore resulted in a loss or injury to the interests of another, and it has seemed essential for the uniform development of all branches of medical science in every medical school, that a generous provision of funds be actively sought and then so distributed, according to plans matured and agreed to by the Association, as to serve the best interests of all institutions and of the public.

Looking to the comfort and welfare of visiting physicians and surgeons, the Association contemplates establishing a central residence or meeting place with provision for social life on lines similar to those developing in London and Paris in anticipation of the need of such professional homes for visiting Americans and Colonials. One of the duties of the New York Association will be to see that those seeking opportunities in clinical, laboratory, or field work, which may be better provided elsewhere than in the metropolitan area of New York shall be promptly directed to the best teachers and best facilities wherever they are to be found in this country or in Canada. Cooperation with the committees in London and Paris, which are organizing the medical resources of England and France for the benefit of visitors from the Americas, will be favored, and this may prove to be one means to return in part the courtesies and assistance the American Medical Officers received without stint from their colleagues during service overseas.

Though New York possesses, to even a greater degree than those cities, most of the elements that made Berlin and Vienna world medical centers, it has not been previously prepared to supply the

demands of post-graduate students. Furthermore, a broad distribution of this store-house of accumulated scientific knowledge that might and should be applied to the prevention of disease and healing of the sick, has not previously received anywhere in this country its fair share of attention from the genius of American organization and liberality. This Association now desires through proper organization and the procurement and employment of an efficient endowment, to foster such use of this possessed knowledge and facilities as will result in widespread benefit to the whole country.

Typhus Spreads in Poland.—According to reports received by officials connected with the American Sanitary Expedition, now on its way through Germany to Poland, there are at present in the latter country 170,000 cases of typhus fever. The Polish Department of Health has appealed to all the allied governments for aid in checking the spread of typhus. Germany is furnishing its delousing equipment and cooperating in transporting medical supplies. Allied medical staffs will be detached and will cooperate with the Polish health authorities.

The Liquor Law for Druggists and Physicians Explained.—William H. Edwards, Internal Revenue Collector for the Second District, in an attempt to make clear the rights of druggists under the war prohibition law in filling prescriptions for liquor says, "Under a new Treasury decision, any licensed pharmacist or druggist may fill a prescription for liquor if his name appears on the prescription in the physician's handwriting and if he has made application and received permit form 737, in accordance with the provisions of Treasury decision 2788, and, further, if he has qualified as a retail liquor dealer by the payment of a special tax. No such prescription may be refilled. Druggists filling these prescriptions shall preserve a copy of every prescription filled and once a month shall transmit to the office of the Collector of Internal Revenue a list showing the names of the physicians, the names of the patients, and the total quantity dispensed to each patient during the month. The regulations provide that the quantity prescribed for a single patient at a given time shall not exceed one quart. In no case shall a physician prescribe alcoholic liquors unless the patient is under his constant personal supervision. The physician shall keep a record in which a separate page or pages shall be allotted each patient for whom alcoholic liquors are prescribed, and shall enter therein, under the patient's name and address, the date of each prescription, amount and kind of liquor dispensed by each prescription, and the name of the pharmacist filling the same."

Antidrug Law Fails Up-State.—A review of the reports received from various counties throughout New York State shows that the Whitney antinarcotic law is almost wholly inoperative outside of New York City, because of the failure of the Legislature which passed the act to appropriate the necessary funds for administration. The act carried an appropriation of $25,000, which was barely enough to establish and maintain for a year the executive offices in Albany. The State Department of Drug Control has announced that in view of the lack of funds to carry out the provisions of the act, it will have to depend upon individual doctors to report to the health authorities of the various counties drug addicts encountered in private practice. Thus far the health authorities have received practically no reports from doctors. It is probable that this condition may result in an illicit traffic in drugs outside of New York City that will render the registration in that city a farce. A drug clinic for addicts has been established in Albany and another will be opened in Buffalo.

Illegal Practitioners Face Prosecution.—Nicholas D. Clements, who has confessed to selling in the neighborhood of one hundred bogus diplomas to would be "physicians," "druggists" and "dentists," was recently brought from Dannemora prison where he is serving a term of two and one-half years for having sold talcum powder as aspirin, to assist the District Attorney in his search for persons practising medicine illegally. It is reported that a number of these men face prosecution. The diplomas sold by Clements for sums ranging from $100 to $150 purport to be from the Southern Medical Institute of Atlanta, an institution which went out of existence some fifteen years ago.

Hospital Buys New Site.—The Hahnemann Hospital property at Sixty-seventh Street and Park Avenue has been sold and a new site for the hospital purchased on the East side of Fifth Avenue between 105th and 106th Streets, running 150 feet in each street. Other adjoining properties have been purchased giving the hospital a plot the total area of which is 30,000 square feet. Plans have been made to begin the construction of the new hospital building at an early date.

Panama to Have Large Hospital.—Plans formulated by President Porras have just been made public announcing that the city of Panama is to have a new hospital which will consist of a system of units and will cover from eight to ten hectares of land in the outskirts of the city. The hospital will provide accommodations for 400 patients. President Porras plans to bring to Panama several distinguished medical men and hospital architects to advise on the construction of the hospital buildings.

Bronxville Opens Convalescent Home.—A convalescent home at Bronxville for discharged men from overseas suffering from nervous troubles has been opened and is now filled with patients. The home is maintained by the Seabury Society of New York and will take other patients of this class when vacancies occur.

Health Department Gets Hospital for Drug Addicts.—Secretary of the Navy Daniels recently granted permission for the use of the buildings at the Pelham Bay Naval Training Station by New York City for the treatment of drug addicts, but strong opposition was offered by residents of City Island who held several mass meetings and employed counsel to protest against this use of the barracks. They claimed that it was a matter of record that 60 per cent. of drug addicts are persons of criminal tendencies and they objected to

the presence of such folks in their community. So the Commissioner has taken possession of Sea View Hospital on Staten Island, turning out the tuberculous sufferers for whom the hospital was built.

Women Doctors to Hold Six Weeks Conference.—A six weeks international conference will be held in New York City, beginning September 15, at which social problems affecting women throughout the world will be discussed. The conference will be under the auspices of the Social Morality Committee, War Work Council, of the National Board of the Young Women's Christian Association. The conference will be divided into three sections: Health, the psychological aspects of the sex question, and legislative measures as they reflect the present status of sex morality. Already a number of prominent women physicians from all parts of the world have accepted invitations to be present.

Economic Conditions a Health Menace.—The Bureau of Preventable Diseases of the New York City Health Department, under the supervision of Dr. Louis I. Harris, has just published the results of a pioneer investigation into some of the medical aspects of the high cost of living. This report is an outline of the living conditions of 2,084 families 60 per cent. of which were investigated by visiting nurses in their work of supervising tuberculosis and the remainder in the course of supervision of diphtheria and scarlet fever. The average number of persons per family was 5.08 and the average number of children 2.69. Of these families, which might be regarded as a typical cross-section of conditions in New York City, 21 per cent. had a total income of $600 per year or less; an additional 30.5 per cent. had a total income of from $600 to $900 per year. A summary of the immediate influence of the increased cost of living on the normal dietary of the families which were the subject of study shows that in 807, or 37 per cent., meat was entirely eliminated from the dietary. In 388 families, or 17 per cent., the amount of meat was appreciably reduced. In 882 families eggs were eliminated from the dietary; in 615 families the use of butter was entirely eliminated. Special attention given to ascertaining the effect on the dietary of children of the high cost of living showed that in 293 families the use of bottle milk was given up, all but eleven of these families substituting loose milk. In 532 families eggs were eliminated from the diet of children. Extreme care was exercised to ascertain as far as possible whether recovery from illness was actually retarded or otherwise affected as a result of inability to purchase food stuffs. It was found that out of a total of 2,183 cases of illness, or a little over 13 per cent., recovery was very definitely retarded because of the increased cost of the essentials of life. The report asserts that not so much emphasis is to be laid at this time on the particular details brought out as upon the fact that surveys of this kind made from time to time must throw a flood of light upon the influences affecting the care of the sick in so far as private practice, hospital care, and public health supervision are concerned. It is hoped that private physicians will discern in this study evidences of the help they may derive from the cooperation of humane, sympathetic, and intelligent nurses and that they will welcome in increasing measure the assistance which these public health nurses are ready to give. The report further declares that the investigation cannot but help to give to one whose point of view is at all altruistic a revelation of the need for health insurance. The study is also of value because it tends to show the necessity for a careful investigation of general and individual conditions in order that medical advice and treatment shall be given which shall reflect a knowledge of general and individual conditions which will enable a physician to avoid giving counsel of an impractical character.

Christian Scientist Healers Held as Child Slayers.—A man and his wife living in Newark have been held on an indictment charging them with manslaughter in connection with the death of their eight-year-old daughter who died of diphtheria, on May 4, while under treatment by a Christian Science healer. The indictment charges that the parents of this child "feloniously did kill and slay."

New York Hospitals to Treat Insured Soldiers.—The United States Public Health Service announces that on August 15 it will take over the Polyclinic Hospital and use it exclusively for the treatment of war risk insurance cases. The Public Health Service, in June, took over the old Hudson Street Hospital for use for the same purpose by the Navy. There are accommodations for 450 patients in the Polyclinic and for 120 in the Hudson Street Hospital. Major James L. Robinson is in charge of the former and Dr. Richard A. Kearney of the latter institution.

Motor Deaths Increase.—The report of the National Highways Protective Society shows a sharp increase in the number of fatalities from automobile accidents for the month of July over the same month last year. In New York City automobiles caused the death of 58, trolleys 10, and wagons 2, as compared with 44 by automobiles, 6 by surface cars, and 2 by wagons in 1918. In the State 128 persons were killed by automobiles, against 96 for July, 1918. The report from New Jersey shows 24 persons killed by motor cars, 2 by trolley cars, and 1 by wagon. Thirteen were killed at grade crossings.

Charitable Bequests.—The will of the late William H. White of Cold Spring Harbor makes a number of large bequests to philanthropy among which are included the following: St. Luke's Hospital, New York, $609,548.78; St. John's Hospital, Brooklyn, $20,000; Nassau Hospital, Mineola, L. I., $10,000; Staten Island Hospital, $40,000 and St. Luke's Hospital, San Francisco, $20,000.

Institutional Positions for Physicians.—The Civil Service Commission, Albany, N. Y., announces the following examinations to fill vacancies in State institutions: *Assistant Physician,* Regular or Homeopathic, for the position of assistant physician in the State hospitals and for other positions of a similar nature in various State and county institutions. The salary is $1,200 with increase each year to $1,600. Unmar-

ried men are preferred. *Assistant Medical Officer*, Department of Health of the Port of New York, at a salary of $1,500 per year, with maintenance. This position is open to men only. *Assistant Surgeon* to the Soldiers' and Sailors' Home at Bath, N. Y. This position is open to men only and pays a salary of $1,560 per year and maintenance. *Bacteriologist* to the State Department of Health. This position is open to men only between the ages of 25 and 40 years and pays a salary of $2,000 to $2,500. A degree in medicine or an equivalent is required. Applications should be received at the office of the State Civil Service Commission, Albany, N. Y., before August 20, 1919.

Obituary Notes.—Dr. ROBERT S. BOSHER, a graduate of the Medical College of Virginia, in 1900, died after a brief illness at his home in Richmond, Va., on July 20, aged 44 years. Dr. Bosher was associate in medicine of the Medical College of Virginia for nearly twenty years, one of the founders of the Stuart Circle Hospital, and for many years a member of the visiting staff of that institution.

Dr. HANSON T. A. LEMON, a graduate of George Washington University, in 1896, died after a brief illness at his home in Washington, D. C., aged 50 years.

Dr. FREDERICK W. WEBER, a graduate of the Baltimore University School of Medicine, in 1888, died after a long illness at his home in Baltimore, on July 22, aged 69 years.

Dr. JAMES B. SIMMONDS, formerly of Marsh Market, Va., a graduate, University College of Medicine, Richmond, Va., in 1898, died at his home in Highland Park, Va., following a stroke of apoplexy, on July 24.

Dr. FREDERICK B. LYON, a graduate of the Northwestern Medical School, Chicago, in 1903, died suddenly of heart disease at his home in Wichita, Kan., on July 20, aged 39 years.

Dr. WILTON R. STUART, a graduate of the College of Physicians and Surgeons of Baltimore, in 1880, died at his home in White Post, Va., on July 24, aged 64 years.

Dr. FRANKLIN H. GOOD died at Reading, Pa., on July 25 at the age of 64 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1878.

Dr. FRANKLIN S. BOWER died at Philadelphia on August 1 at the age of 60 years. He was graduated from the College of Physicians and Surgeons of Baltimore in the class of 1881. He was the first President of the Samaritan Hospital.

Correspondence.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, July 15, 1919.

Welfare Work for French Children.—A meeting was recently called by the president of the "Association des Dames Françaises" to consult with officers of the American Red Cross with the purpose to take over from the latter, the promotion of "Children Welfare Work in France." Dr. William J. French, of Washington, D. C., in charge of the medical service, spoke on "Medical Social Service." Other speakers were: Miss Frances Stern, chief of the Social Center, on "Social Service in Relation to Medical Work"; Miss Layton, on "Relief Work as an Aid to Medical Service"; Miss Jane A. Moore, on "Home Visiting," and Mme. Gabrielle Magnin, on "Food in Relation to Medical Service." The speakers all emphasized the necessity of carrying on the work started by the American Red Cross, after that organization is recalled to America.

The American Red Cross started its work in the 19th Arrondissement, one of the most populous in Paris, on February 15, 1919, with a children's clinic at 2 rue des Mignottes. In April, a nursing clinic for nursing mothers, at 9 rue Edouard-Pailleron, was taken over, and another children's clinic opened at 28 rue de l'Argonne. While at first the work attempted was purely clinical, it was later decided to unite the three clinics under one head, and attempt to put in operation a social program as well. To this end, each clinic was organized along the same lines. The organization consisted of an American chief nurse, with an interpreter when needed, and French aids, an American doctor being present at each consultation. The work was expanded so that two children's consultations and two nursing consultations were given each week at each of the clinics. Not only sick children but also healthy children were encouraged to come to these consultations at regular intervals—the sick children to have their ailments treated and the healthy ones to prevent their becoming ill. Especially is this necessary in the case of babies in arms, for whom regulations or advice relative to feeding and general care are of such vital importance.

The following system has been put into operation: Each child on entering the clinic for the first time is registered, and certain social questions are asked—for instance, as to the health of father, mother, brothers and sisters; previous illnesses, tuberculosis contact, etc. The child is then passed to the doctor, who makes a thorough and careful examination. In examining these children it is discovered that the vast majority of them have no definite illness or disease, but that they are in bad sanitary condition, anemic or suffering from malnutrition. The child's condition is talked over with the parent who accompanies it. The parent is made to feel that the doctor, the nurse, the whole personnel of the clinic, take a particular interest in the child and in its family, and in a friendly way, advice is given relative to food, fresh air, general hygiene, etc. At the earliest possible moment after the visit to the consultation, the nurse, who is also a trained social worker, makes a visit to the home, taking with her the record of the case obtained in the clinic. The information there obtained is now supplemented by personal observation and careful notes are made of the conditions found in the home. Inquiries are also made as to the income of the family, the number of people working, what they do, and how much money is spent. The social history is supplemented by any additional information which it is not possible to get at the time of the visit to the clinic.

A social organization such as this cannot hope

to succeed if it works alone. It must be connected with other social agencies. This has been attempted by establishing friendly relations with the Mairie, other philanthropic organizations in the 19th Arrondissement, the schools, the local doctors, and various religious orginzations. The founders of the clinics hope, therefore, that when the American Red Cross is obliged to leave the French organization first named will take up the reins, as, should the present splendid organization be lost to France, it may be years before another like it is established.

Death of Captain Aupperlee.—News has been received of the death of Captain Harold Aupperlee, of the Commission to Serbia, American Red Cross, from typhus fever, at Nova Varosh, Serbia. Captain Aupperlee, whose home was in Grand Junction, Col., began his service in Serbia, in June, 1917, with a Stanford University Ambulance Unit. In November he came to Paris, expecting to join the army. The Red Cross was sending workers to Salonica for the relief of Serbian refugees and Captain Aupperlee was requested to join the expedition. For a year he worked in Salonica, under most trying conditions, and when the Serbians made their offensive in September, 1918, his detachment of Red Cross ambulances and camions followed them and helped to care for the wounded. With the liberation of Serbia typhus spread like a plague among the returned exiles. American doctors and nurses were sent to northern and southern Serbia. Captain Aupperlee went to Belgrade and established general headquarters, warehouses, and barracks. He had charge of all Red Cross transportation until April last, when he was sent with a physician in response to an urgent request for aid from an isolated district near Albania. By trips on horseback and in oxcart, ten carloads of goods were distributed before Captain Aupperlee was taken ill. Funeral services for him were held in Belgrade and a company of Serbian soldiers accompanied the body to the grave on a hill overlooking the Danube.

OUR LETTER FROM GENEVA.

GENEVA, July 1, 1919.

Hyperpeptic Gastritis.—An interesting morbid process has been studied during the war by some French army surgeons and called by them "soldiers' hyperpeptic gastritis." The clinical symptoms are pain, discomfort, vomiting of food, which is not often bloodstained, an inclination to constipation rather than diarrhea, and generally a drop in the blood-pressure. Analysis of the gastric contents shows a marked hyperchlorhydria and considerable free hydrochloric acid. The cytological examination after lavage of the gastric contents shows numerous cells, more or less intact, eosinophiles or not, exuberant or normal, and a varying number of polynuclear leucocytes. Some cases offer only an epithelial desquamation, the cell elements having a normal shape and reaction, but they are fragile, and unquestionably come from the mucosa. In another class of cases there is a pronounced leucocytic reaction of the polynuclear and a few lymphocytes. The first class may be regarded as hyperpeptic gastritis, perhaps hyperplastic, while the second may be regarded as inflammatory gastritis.

During the acute paroxysms, the appearance of red blood corpuscles and albumin in the lavage, occasionally albumin alone, would seem to indicate an added ulcerating or erosive process which clinically gives rise to a mild febrile reaction. Hyperplastic or hyperpepitic gastritis of the soldier is, consequently, characterized by its chemical and cytological reactions. The acid liquid and the free hydrochloric acid after a night's fasting identify the functional disturbance, while the presence of the epithelial cells or leucocytic elements indicates that there is either an inflammatory or an irritative lesion of the mucosa, as the case may be.

In some cases the men suffered from mild gastric symptoms before the war, and service in the army merely aggravated the condition. In some the dentition was faulty, while others had formerly suffered from various infectious diseases, such as typhoid or dysentery; several had been gassed, and in them the gastric process was probably toxic. But a greater number had no antecedent history of gastric trouble, and it is therefore probable that the diet was at fault. An excess of meat, often canned, likewise an excess of both wine and coffee, would seem to be responsible for the gastric process. These are products of medium toxicity which would not produce serious, deep-seated lesions, but the action of which as a secretory, or perhaps even a hypergenetic, excitant, cannot be denied. Meat alone, or an excessive or a too exclusive meat diet, may bring about reactions which become permanent and in the end produce a durable lesion of the gastric mucosa. It would therefore seem that there are reactions and irritation resulting from the diet, while septic inflammation likewise exists. Loeper and Verpy are inclined to suspect that the former result in a hypergenesis, while the latter produces diapedetic lesions. To a certain extent cytodiagnosis permits one to make a classification and to differentiate the cases, but the functional result is the same, namely, an acid liquid, rich in HCl, can be obtained after a night's fasting.

It is possible that there may be a predominance of the morbid process in a given region of the stomach, such as the pylorus, mesogastrium, or the cardiac portion of the organ, but as no case has come to autopsy this question must remain in the domain of an hypothesis. Gastritis of the pylorus, cardia, or lesser curvature is undoubtedly responsible for certain clinical differences, but the predominance of such or such symptom is not enough for making a diagnosis of limitation of the lesions to a certain area of the stomach.

The foremost therapeutic indication is a strict diet, with absolute proscription of meat in any form, and one that is poor in nitrogenous substances, such as milk, potatoes, and farinaceous foods. In cases of gastritis with vomiting lactose water as a drink given for several days and soups made with potatoes, carrots, and green vegetables, but without peas, stringbeans, or lentils, will be found to work well. Salt is prohibited, at least during the first part of the treatment. Sugar solutions are soothing, and produce by their concentration a mucous exudate as well as an increase of calories. A sugar diet, or even a forced sugar diet,

which was advocated some six years ago, I believe, by Loeper of Paris, for gastric ulcer, will be found of great value in the cases under consideration, as that is a distinct depressor of the gastric secretions. By diet alone the acidity may be made to drop below the normal, the cell reaction subsides, and the secretion during fast disappears. But it is absolutely necessary to continue it for a prolonged period of time, otherwise a recurrence is fairly certain to ensue.

From the viewpoint of medication, there are three principles to follow, namely, gastric lavage with weak bicarbonate solutions, the absorption one-half hour before meals of a phosphated or sulphated solution, similar to those prescribed by Bourget or Hayem, in which the citrate of sodium may advantageously replace the bicarbonate. Lastly, the exhibition of bismuth for coating the gastric walls, taken on an empty stomach. Bismuth carbonate is preferable and should at first be prescribed at the dose of fifteen to twenty grams, while later on the dose is reduced to three or four grams.

A German Professor True to Form.—Prof. Sauerbruch, a German, until recently professor of surgery at the University of Zurich, Switzerland, and chief of the cantonal hospital of that city, has recently been in the limelight and received the honors of a discussion which took place in the hall of the city fathers of that town. It appears from words exchanged during the debate on the administration of the budget for the year 1917, between a deputy and the chief of the department of health, that Dr. Sauerbruch had been authorized to have copies made of some *x*-ray plates belonging to the Roentgen Institute. This institute is an annex of the cantonal hospital and from this fact Sauerbruch was also the director. Now, the illustrious doctor carried away with him to Munich not only the copies but also a certain number of the original plates.

As no catalogue was kept, it has been impossible to estimate how many plates were taken by the German professor. At the meeting alluded to this operation was qualified as it deserves to be. As to public opinion of Zurich, it shows little tenderness for this foreigner who, besides other vexations that he caused, appropriated documents belonging to a public institution which cannot be replaced.

The Working of Health Insurance in Germany.—Quite recently, the *Kölnische Zeitung* reminded its readers that every political party in Germany, including the most extreme Socialists, were united in praising the medical profession for its devotion, skill, and self-sacrifice during the war. But physicians cannot live merely by fine words, and the National Assembly, without protest from any of the political parties, has sanctioned alterations in the regulations for compulsory insurance that will ruin the profession. Before the war, the compulsory insurance scheme applied to the laboring classes and to those who earned incomes less than $625 per annum. Persons who could satisfy the authorities that their earned incomes did not exceed $1,000 per annum were also permitted to join the scheme if they so desired. The fees which physicians received on behalf of those insured persons worked out to not more than eight cents a visit, with the result that to make a living a physician had either to undertake more work than his own health or his medical conscience could justify, or to increase his income by private practice.

The Center brought up a proposal to raise the limit of compulsory insurance to incomes of $1,000 per annum, and of voluntary insurance to $1,500. The Socialists proposed that the compulsory limit should be $1,500 and that there should be no limit to voluntary insurance. The Socialist scheme was adopted, with the result, it is rumored, that some 21,100,000 persons who formerly were private patients will now be under the insurance scheme —and the medical profession will be ruined.

Rumored Execution of Dr. Lindmann.—It is rumored here that Lindmann, the editor of the *Münchener medizinische Wochenschrift,* was among the hostages executed recently at Münich by the Spartacan insurrectionists.

3. Cardiovascular Response to Infection.—Samuel E. Earp discusses the influence of the extracardial and intracardial nerves on the heart muscle, and points out that fever may be considered as a symptom of stimulation produced by small amounts of toxins, and collapse as a symptom of paralysis caused by larger amounts of these substances. During the influenza epidemic, the absence of ratio between pulse, respiration and temperature was frequently noticed. Many cases presented toxic heart muscle favoring dilatation and functional valvular lesions, but principally myocardial lesions. The presence of a toxic myocardium was observed so frequently that the author has referred to it as an influenzal myocardium. In some cases there was failure of coaptation of the valves with functional murmurs which disappeared during convalescence. Delafield has pointed out that in acute infectious diseases, such as influenza or pyemia, the media and intima of the coronary arteries may be involved in necrotic and hyperplastic processes which are of great significance in leading to certain forms of sclerosis of the vessels, a fact which shows why the heart muscle, and all which relates to it, may easily become defective. The nutritive supply to the heart is thus lessened, and if the condition is chronic we recognize why chronic myocarditis and endocarditis eventually have a permanent decompensation, thus shortening the life of the patient. Delafield has also stated that the streptococcus and staphylococcus are the most common causes of a diseased condition of heart muscle, again suggesting conditions found during the influenza epidemic. Moreover, Thomas Lewis states that we are not justified in attributing the whole breathlessness of lobar pneumonia to lung damage, since pneumococcic lesions in other parts of the body may also be associated with breathlessness, a nonvolatile acidosis being given as the principal agent. When heart failure is added the breathlessness is governed by the quantity of nonvolatile acid present and the deficiency of aeration, with resultant hyperemia. Since the beginning of the war more attention has been given to mitral stenosis and the result of streptococcic infection on the heart, and the importance of the prevention of streptococcus infection has been pointed out by Cumming, Spruit, and Allen. In the past physicians have been inclined to lay too much

stress on the importance of valvular lesions to the exclusion of myocardial lesions; and this is equally true of the textbooks. This is explained partly by the fact that in chronic cases of cardiac disorder in which the heart muscle is primarily at fault, there exist no lesions which the pathologist can describe in objective terms. Christian has reported 407 cases of cardiac insufficiency from myocardial disturbance without organic lesion of the heart valves. Cases of infectious endocarditis have been reported by Lutembacher and Scheltema, and Pugol reports a series of cases in which myocarditis was due to sepsis from the oral cavity. Many of the war wound heart cases were really septicemia cases, the Streptococcus pyogenes being present. Speaking of purulent bronchitis, Hammond has called attention to three groups of changes in the morbid anatomy: (a) The lung condition, the smaller bronchi being filled with thick pus, from which air is absent; (b) evidence of toxemia, especially in kidneys, spleen, liver, lymphatic glands, and heart muscle; (c) signs of right side heart failure and passive congestion. Influenza complicated with pneumonia almost inevitably involves the heart. Mackenzie considers that a severe attack of influenza with pneumonia is not really one of heart disease, but of intense intoxication of the cardiac system, and that therefore stimulants are useless. He holds that since the damage is not limited to the heart, treatment should be directed to increasing the power of resistance and the elimination of the poison and healthy renewal of injured tissues.

7. Hypertrophic Pulmonary Osteo-Arthropathy (Bamberger-Marie Disease); Report of a Case Following Lung Abscess.—Seward Erdman reports in some detail a case of draining lung abscess associated with enormous enlargement of the hands and feet, with ossifying periostitis of certain long bones, and with fluid in the knee joints—evidently a case of subacute infectious osteo-arthritis. The author draws particular attention to the absence of clubbing of the fingers in the case under consideration, as in the cases reported in the literature emphasis is laid on the presence of this sign. The present case is therefore a direct contradiction to Sternberg's statement that "we see clubbed fingers without periosteal changes in the long bones, but we do not see the reverse." The history, the clinical findings, and the roentgenologic findings in the case reported all point quite conclusively to the diagnosis of hypertropic pulmonary osteoarthropathy, by which is meant a subacute infectious osteo-arthritis, secondary to a secondary focus in the lungs, and the author points out that the roentgenogram of the skull shows an abnormally small sella turcica, and that, therefore, the possibility of some change in the pituitary must be admitted. He is also of the opinion that, like the first case of this disease reported by Marie in 1890, the present case may later develop into an irregular type of acromegaly. The roentgenograms illustrating the case were done by Captain Walter A. Ostendorf.

3. Eye-color and the Abnormal Palate in Neuroses and Psychoses. H. Laing Gordon.
4. A Case of Pituitary Tumor Treated by Operation. H. Lawson Whale.

2. On the Prognosis of Nerve Injuries.—Robert Kennedy draws attention to the length of time required for the functional recovery of nerve injuries, the reason being two-fold: the occurrence of nerve degeneration after all but the most trivial injuries and the necessity of nerve regeneration before conductivity is regained, and the degeneration in the muscles supplied by the damaged nerve. This degeneration of muscles takes place with great rapidity, and is such that the muscle cannot become functional again until it has regenerated and this restoration cannot begin until the nerve has already regained its conductivity. Then there is the difficulty of keeping the case under observation long enough—usually for several years—to estimate properly the prognosis. In nerve injuries many factors enter into the prognosis. (1) Sepsis or asepsis. Sepsis, though one of the most unfavorable factors, is not a complete bar to recovery, but it is apt to lead to changes in the nerve trunk and its surroundings, resulting in the formation of cicatricial tissue and permanent damage to the nerve trunk. In the war, most cases were associated with sepsis, in contrast to those seen in civil life, and consequently recovery was more rapid as a rule in the latter. Absence of sepsis, however, does not mean assured recovery, as, for example, in cases where there is no open wound but where the nerve cut by sharp fragments of a fractured bone or has been ruptured by tension. (2) The nature of the damage to the nerve trunk. This may vary between slight compression by a cicatricial band and extensive loss of nerve substance. In general, compression is regarded as more favorable than severance, yet the results of the two types are practically the same. (3) The surroundings of the damaged nerve trunk. This is important since, even though the nerve may be in a condition for recovery, the development of a mass of densely contracted cicatricial tissue makes recovery impossible, and this is particularly true in the case of the ulnar sulcus and the aqueduct of Fallopius. (4) Amount of trauma. A clean cut of course gives a better prognosis than a laceration, the harmful effect of trauma being due to the reaction in the tissues, in the nerve itself, and in the surroundings, leading to development of cicatricial tissue, and ultimately compression. (5) The nerves injured and situation of the injury. Prognosis is less favorable in injury of some nerves than in that of others. Injuries of the facial nerve are difficult to repair. Injury of the aqueduct is practically impossible to deal with because of the surroundings of bone ;also if injured in its course in the parotid its repair is very unfavorable because of the salivary gland, while beyond the parotid the tenuity of its branches is against the chances of a favorable reunion. In general, up to a certain size, the larger the nerve trunk the more likely is the result to be good; the larger trunks are more easily found with less damage to tissues, and the interval between the ends is less in proportion to the thickness. Again, the same nerve has a better prognosis in certain situations than in others; for instance, the ulnar nerve has its worst prognosis when wounded in the course of the ulnar sulcu unless operative means are adopted to overcome this. The lapse of time between injury and operation is also a factor of great importance. The progressive atrophy of muscle is the most serious factor of a nerve lesion. Changes take place in the muscle which almost immediately affect its electrical reactions; it retains

its responses to galvanic stimuli, but continues to waste and recovery of motion will not occur until the muscle is restored to a condition in which its electrical reactions are normal. Recovery of faradic irritability is, as a rule, the immediate precursor of voluntary contraction. Delay in operation usually means more protracted recovery. In considering the relative advantages of primary and secondary suture, it may be said that other things being equal the advantage lies with primary suture. In the war, however, the wound has been lacerated and infected in most cases, and therefore not in a condition for primary suture, which has resulted in failure. In any case, unless there is proof that the nerve is reuniting, secondary operation should not be postponed more than four months. Experience has shown that cases operated upon within three months, when primary suture has not been done, give a commencing recovery in the muscles in three and a half to four months, whereas those not operated upon for five or six months do not show any improvement for seven or eight months. When operation is done only after long intervals, recovery is so remote and so gradual that it is difficult to say when it has commenced, but even after long periods there is a possibility of obtaining good results. In regard to factors occurring at operation, the author points out that a higher standard of aseptic technique is required than in the case of other branches of operative surgery, the reason being that we are dealing with the renegeration of one of the highest types of tissue cells, inferior to connective tissue cells in regenerative capacity. Particular care should also be taken to avoid force or coarse manipulative handling. In coapting the nerve ends, there is danger of rupturing the fibres if too great tension is exerted. If the ends do not quite meet conductivity is restored in some cases. Excising a segment of bone so as to shorten the limb and bring the nerve ends into contact requires so much manipulation that prognosis is unfavorable. The suture must be carefully chosen in view of its capacity to be encapsulated by the tissue or absorbed, so as to cause the least irritation, and the smallest possible amount of foreign material should be used. Prognosis is poor in cases where the sutured or liberated nerve has unavoidably been left in a bed of scar or in a bony canal or furrow. Post-operative factors may also affect prognosis. Contraction of antagonist muscles can be prevented by appropriate fixation or passive movements, and attention to this is particularly necessary in cases of delayed recovery. In cases in which sensation was present after receipt of the wound, but was lost gradually at no great time after the injury, it will usually be found that the nerve is not divided but compressed in cicatrix. Overwork of muscles must be avoided on recovery. The author appends the results of a series of 25 cases which have been observed for a sufficiently long time, in 18 of which there was complete success, *i.e.* normal function was restored, and in 11 of which there was partial success, *i.e.* recovery was sufficient to give distinct improvement; failures, *i.e.* cases in which no useful recovery resulted, were nil.

4. The Cure of Multiple Warts on the Face.—Charles Ind reports a method which he has devised for the cure of multiple warts and which is a combination of two methods suggested by different dermatologists. The warts and surrounding skin are painted three times a day for one day with a saturated alcoholic solution of salicylic acid, as recommended by Stelwagon, and on the following morning the warts are cut off by a flat, sharp steel instrument, beveled on one side only; this passes freely over the healthy skin, but when it comes to the wart cuts it off, leaving a slightly bleeding point. The surface is painted at once wtih the salicylic solution, and twice more later during the same day, three times in all. This turns the little red spots to a brownish-black color, tiny scabs form, which are allowed to drop off, taking about a week to do so, and leaving a perfectly clear, healthy skin. The forehead is bathed with pure alcohol once a day until the scabs have all dropped off. The author points out that a razor is no use, a sharp, flat instrument pushed over the skin being necessary; there is neither pain nor scarring; sepsis does not occur; the treatment is useless for larger warts; the use of the salicylic solution prevents pain when the warts are cut off and recurrences afterwards.

2. The Treatment of Hemophilia.—D. C. Bamhill says that in the treatment of hemophilia in the extraction of teeth the following formulae of Prinz has proven highly satisfactory in the hands of many practitioners, including himself: Calcium lactate, 6; aromatic syrup, 30; distilled water, 90. A teaspoonful every two hours for 24 hours, the entire quantity being taken within that time. If such a preparatory treatment is employed, the chances of postoperative hemorrhage are materially lessened, but in case this treatment has not been used or if it fails, Bamhill employs the following treatment: Where blood vessels within bony canals are lacerated and where it is inadvisable to use the cautery, another of Prinz's remedies will prove very effective: White wax, seven parts; olive oil, two parts; carbolic acid, one part. Melt the wax, add two parts olive oil and one part carbolic acid; pour this upon cold sterile water, which will cause the mass to congeal. Then take a liberal sized portion of the wax compound and with a suitable instrument or the finger and thumb force it into the canal, which will usually block the hemorrhage at that point. One will not find many cases where it is necessary to use the wax, but it is an excellent agent when indicated. Whether or not the author has used the wax, he takes a large pledget of cotton for each socket, one that is larger than the socket will accommodate. Bamhill uses Monsell's solution for saturating the pledgets. Pack one of these oversized pledgets tightly into each socket. The treatment is usually sufficient, but for those persistent bleeders, in addition to the treatment just described, take a gauze napkin and wrap it around a piece of absorbent cotton. Saturate this with Monsell's solution and place it in the mouth over the cotton pledgets already inserted in the wounds. The roll of cotton should be sufficiently thick that when the jaws are bound together there will be sufficient room between the anterior teeth to permit of the introduction of a feeding tube. Then by means of a Barton's bandage you render the lower jaw immobile. Now put your patient on the calcium lactate treatment and if the hemorrhage is not entirely controlled within a period of twenty-four hours, or if you have reason to feel alarmed about the condition earlier, call in a physician and ask him if he will not administer anywhere from 10 to 30 c.c. of normal horse serum. The packing should be removed at the end of twenty-four hours.

7. The Independent Medical Journal.—George L. Servoss holds that an independent medical journal, like any other independent thing, should be just what its name implies. It should have a mind of its own and then, in the words of Roosevelt, "have the nerve" to give expression to the thoughts coming from that mind; and without the fear of any criticism that might follow. Its editors should be fearless; providing, of course, that what they might say should at all times be truth. Those editors should not be at the beck and call of anyone but themselves and should remain absolutely independent any time and all the time.

It has been intimated by some few people that there

is no place under the sun or elsewhere, for that matter, for the independent journal. It has been classed with the things "indecent" and called a lot of other names. But there are others who contend those journals have a place, a real place. If nothing else, they act as a sort of balance or counterbalance. Were it not for the independent journals we would have absolutely nothing in the way of democracy. The profession would be wholly and solely under the control of cliques, and no one could imagine such a thing as fair play or a square deal. And the independent journals are really the "newspapers" of medical literature, for it is the independent that invariably gives us the first inklings of the later ideas and things connected with medicine. They do this for the reason that they are under no restrictions and so can publish what they please and when they please. The author believes that the independent journals give their readers better literary material than do any other current publications. They do this because they can pick and choose that which they print and do not print things simply because such is their obligation.

La Presse Médicale.

May 8, 1919.

Relation of Human Grippe to Certain Animal Pasteurelloses.—Orticoni, Barbie, and Augé have collaborated on an important paper on this subject. They begin by the assumption that pandemic influenza is quite different from cold weather annual grippe. The latter, while diffusible, is so in a restricted sense as compared to pandemic influenza and confers no immunity. The two should no longer be called by the same name and to the pandemic should be applied the term "septicemic grippe." In winter grippe the high temperature is not an indication of sepsis, for hemoculture is practically negative. Sepsis in the septicemic form may be due to one or more of a variety of microorganisms and most frequently to an association of a coccobacillus with the strepto- or pneumococcus. This coccobacillus is similar to if not the same as Pfeiffer's organism and has not been cultivated from the blood in the mild cases; pneumococcus sepsis tends to occur in affections of the pneumococcus type, while the streptococcus seems responsible for the asphyctic form. While the pneumococcus and streptococcus are well able to kill alone, the coccobacillus is so often found in the fatal case that it must be regarded as a powerful synergist. Veterinaries know of a number of diseases in animals especially in horses which possess points of resemblance to pandemic influenza. Leaving aside contagious pneumonia we have the affection known by the French equivalent of strangles, a protein malady which ordinarily prevails only in the cold months. It is significant that it was very common in the French army horses during the summer of 1918. It has been regarded as due to the streptococcus of Schutz, but this is now claimed to cause only secondary infection. Recent attempts at hemoculture have shown much the same finds as in pandemic influenza. There was an aerobic coccobacillus which showed a polymorphism suggesting that of the pasteurella, although with cultural differences. The pasteurellae can cause a form of hemorrhagic sepsis and often accompany the bacillus mallei in glanders. At the same time they have only low virulence to laboratory animals. It is now claimed that the pasteurella in question is found not only in strangles but in contagious pneumonia. In fact this group of organisms is in evidence in many epizootics, and in many ways resembles the coccobacillus in man. But despite this similarity between human and animal pathology the authors are inclined to the view that pandemic influenza could not occur in the absence of some filtrable virus.

Le Progrès Médical.

May 17, 1919.

Early Diagnosis of Tuberculosis from the Social Viewpoint.—Sergent refers to open or contagious tuberculosis, but since this must be secondary to the closed focus the latter must also be considered in prophylaxis. Hardly any one now disputes that tuberculosis in the adult is only an awakening of tuberculosis contracted in childhood, usually around the second or third year of life. From the seroreactions at the period of puberty about 4 per cent only appear to have escaped. But this early infection represents a sort of immunization, and hence the great majority of those once infected remain immune under ordinary circumstances. The fundamental step in prophylaxis is care of the young child, a system of child hygiene which will protect him against contagion when he begins to creep and carry objects of all kinds into his mouth. Clean floors will contribute greatly to this end. At a much later period we have to protect the adult and adolescent from deterioration which will awaken the latent disease, and other social maladies like alcoholism and syphilis must be antagonized here. The exposure of the healthy to subjects with open tuberculosis is a powerful factor in the spread of the disease, and this holds good for all periods of life, but especially to the young child who creeps upon floors infected with sputa. All of Sergent's recommendations were made 20 years ago, but are made to-day with much greater assurance, and education of the public along these lines is proceeding very slowly, so that one can only harp on the same old strings. The subject of diagnosis of incipient tubercle which is of greatest value for individual prophylaxis has made some advances and this is true especially of radiography, which will quickly disclose a closed or latent focus. Bacteriology and serodiagnosis have been advanced in the early recognition of active tubercle. Many a red cheeked and robust young man may be shown to be tuberculous by refined bacteriological technique. The laboratory has distanced the stethoscope.

Correspondenz-Blatt für Schweizer Aerzte.

May 3, 1919.

Medical Experiences in Asiatic Turkey.—Vischer was stationed in ancient Edessa, now Urfa, in North Mesopotamia. The climate is subtropical, the summers free from rainfall, and the winters mild and relatively wet. The inhabitants are of melting pot type, as many as half a score of nationalities being represented. The author, a medical missionary, was highly regarded by the Mohammedans, although they are anti-Christian, and their fatalism does not allow them to bother much about some ailments. The annual number of patients treated averaged 5000. Among affections seen the following are of interest: Noma was occasionally encountered as a sequel of measles or typhoid. Aleppo boil was extremely common. Malignant growths seem to have been fairly well represented in a community of 50,000, even if less common than in Europe. The locations do not differ much from those in the latter continent, and no racial immunity is mentioned. While in Europe injuries are mostly from machinery, in Urfa they are from weapons. Nearly all men go armed, for robbery is common. Appendicitis is scarce and mild. Hernia and stone in the bladder are of common occurrence. Pneumonia is common, often with empyema as sequela. Rachitic deformities seem very rare, while congenital malformations are common. Trachoma and eye affections in general are very prevalent. The rustics have faultless teeth, while caries is common in town dwellers. Measles and whooping cough are very common, and cause much mortality. Scarlatina and diphtheria are almost unknown. Typhoid is endemic, and nearly every one contracts it, but despite poor care, the mortality is low. The spotted typhus was unknown while the author lived in Urfa. Syphilis is common, and of two sorts. One is venereal, acquired by youth who visit Aleppo, a hotbed of prostitution. The other is familial, inherited, and largely contracted innocently. Favus is so common that the word is a synonym of baldness.

The Influenza Mortality of Rio de Janeiro.—The pandemic appeared in Rio on October 12 and lasted two months. Of a total population of 915,000 about 600,000 were attacked by the disease. The total number of deaths from the disease was nearly 9,000, or more than half the deaths from all causes.—*Revista Medico-Cirurgica do Brazil.*

Book Reviews.

BIDRAG TIL DEN MEDIKAMENTELLE FODSELSHJAELP. KLINISK FORSOK MED KININ, HYPOPHYSIN OG PITUITRIN. AV GEORG BENESTAD. Kristiania: Steen'ske Bogtrykkeri, 1919.

THIS brochure of 171 pages is in reality a supplement to the *Norsk Magazin for Laegevidenskaben* with the date of January. It is not only a very complete monograph on the subject, but contains many original case histories—considerably over one hundred. The entire contents of the volume are thoughtfully summed up in full-faced type, in a few pregnant sentences. Of hypophysis extract, however given, 0.10 gm. of the dried gland substance equals 0.5 pituitrin or 1 cc. of pituglandol or from 1 to 2 cc. of hypophysin. The maximum doses should not exceed twofold the ordinary dose. In general, one dose should be the limit in the period of dilatation, with another during the period of expulsion.

STENOSI ESOFAGIA DA DIAFRAMMI DI SHRAPNELL PENETRATO NEL MEDIASTINO POSTERIORE. Par Prof. ALFONSO POPPI, Chirurgo Comprimario dello Spedale Incaricato di Otorinolaringoiatria nella R. Università di Bologna. Bologna: Gamberini e Parmeggiani, 1918.

THIS brochure is a reprint from the *Bollettino delle Scienze Mediche* for November, 1918. Its most distinguishing feature is a series of five plates, of which one is colored, showing the exact position of the shrapnel projectile in a horizontal section of the victim seen from above downward. The projectile is readily seen in the act of compressing the esophagus. An *x*-ray plate would have been much less illuminating than this diagrammatic view.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia. Assisted by LEIGHTON F. APPLEMAN, M.D. Instructor in Therapeutics, Jefferson Medical College, Philadelphia. June 1, 1919. Price, $6.00 per annum. Philadelphia and New York: Lea and Febiger.

THIS number of Progressive Medicine contains chapters on: Hernia, by W. B. Coley; Surgery of the abdomen, exclusive of hernia, by A. O. Wilensky; Gynecology, by J. G. Clark; Disorders of nutrition and metabolism, diseases of the glands of internal secretion, diseases of the blood and spleen, by E. H. Funk; and Ophthalmology, by W. F. Hardy. Readers of this publication will remember that this is the number which contain's Dr. Clark's valuable summary of the recent advances in connection with the etiology and treatment of cancer. We miss from the list of contributors the names of many whose articles were eagerly looked forward to, and whose contributions were often of more than ordinary value.

COLLOIDS IN BIOLOGY AND MEDICINE. By Prof. H. BECHHOLD, Member of the Royal Institute for Experimental Therapeutics in Frankford a. M. Authorized translation from the second German edition, with notes and emendations by JESSE G. M. BULLOWA, A.B., M.D., Assistant Clinical Professor of Medicine, Fordham University; Adjunct Professor of Clinical Medicine, New York Polyclinic School and Hospital; Visiting Physician, Riverside Sanatorium; Associate Visiting Physician, Willard Parker Hospital, New York City. With 54 illustrations. Price, $5.00. New York: D. Van Nostrand Company, 1919.

THE very great development of organic chemistry during the past few decades has so occupied the attention of investigators that certain other allied subjects have suffered, and although the scientific study of colloids began over fifty years ago, it is only comparatively recently that their investigation has been carried on in a really active way. The fundamental part played by colloids in vital processes is now being recognized, and in the light of this knowledge new and more satisfactory explanations are being found for many of the problems of medicine. For example, Martin H. Fischer's studies on nephritis and edema, although all of his conclusions have not met with universal acceptance, have shown the possibilities that lie in this direction, and it is evident that an almost unexplored field awaits further research. Such phenomena as the action of drugs and disinfectants, the processes of secretion and excretion, immunity, growth and development, the functions of the blood, etc., are all susceptible of new interpretations on the colloidal basis, and promising opportunities exist for studies in regard to these and many other questions. The present volume comprises the most recent summary of all that has been done in the application of colloidal chemistry to biology and medicine, and it is a great satisfaction to have it available in English form. Many topics of much practical importance in addition to those already enumerated are discussed, such as the nephelometer, the ultramicroscope, food preservatives, bread making, tissue fixation, etc. The translation is excellently done, and the frequent editorial notes added by Dr. Bullowa are always illuminating and to the point. One omission of some importance is the absence of any discussion of the significance of the colloidal gold reaction in the spinal fluid, which has become a procedure of great practical value in diagnosis. The volume forms a most complete and readable introduction to the study of colloids, with a full consideration of the rôle they play in biology and medicine, and it should be of great interest to all medical readers.

MANUAL OF EXERCISES FOR THE CORRECTION OF SPEECH DISORDERS. By MAY KIRK SCRIPTURE, B.A., Instructor in Speech, Columbia University (Extension and Summer Session); Director of Speech Correction, Vanderbilt Clinic, Neurological Department, College of Physicians and Surgeons, New York; Special Assistant in Speech Defects Medical Council of New York City Children's Hospital and School Randalls Island; Lecturer at State University of Iowa, 1918; and EUGENE JACKSON, B.A., in Charge of Speech Correction at the University and Bellevue Hospital Medical College Clinics, New York; Teacher for the Correction of Speech Defects, New York Evening Schools. Illustrated. Price, $2.00. Philadelphia: F. A. Davis Company, 1919.

TO one who loves and reveres his native tongue it is a matter of deep congratulation to note the ever-increasing attention paid to the correct use of that tongue, not only its composition and written form but, and especially, its spoken word. Too long have the slovenly habits of speech in both England and America been tolerated and gone uncorrected, and we can but rejoice to note the establishment of schools and classes for the training of the child in correct diction. In these schools the oral lessons must, if they are to be retained by the people, be supplemented by written exercises through which the good end sown in the class may germinate and fructify in the home. An excellent book of this kind is the one before us. Written by two experts in this art, it contains every essential for the correction of the various forms of speech defect, beginning with setting-up and breathing exercises. The book will be useful not only for class instruction, but may profitably be employed in home study and instruction where for one reason or another class work is not possible. An intelligent mother, with the aid of this book, could correct many simple faults of diction in her children, or prevent bad speech habits before they were formed.

A PROPOSITO DEL TRATAMIENTO DE LA EPILEPSIA. Por Dr. MIGUEL ARANGO, Universidad Nacional de Colombia, Colegios Reales de Inghilterra, Escuela de Medicina Tropical de Liverpool, etc. Barranquilla: Tipografia, El Derecho, 1917.

THIS brochure of 103 pages is entirely devoted to a new method of treating an old and practically incurable disease. So far as can be inferred from a perusal of the work the treatment is at best palliative in character, even inferior to the bromides but without the latters' drawbacks. This is the sedation of spinal cord excitability by the intramedullary injection of stovaine. The cases cited do not suggest the existence of idiopathic epilepsy and the alleged cures are too miraculous to accord with the prognosis of the latter. The author is evidently sincere in his contention and is a man of unusual attainments, but the bookwork of the volume is inferior, and the views should be aired in a much better circulating medium. There is a tendency on the author's part to stray into bypaths which have no connection with his subject.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Thirteenth Annual Meeting, Held in Syracuse, May 5-8, 1919.

(Special Report to the MEDICAL RECORD.)

(*Concluded from vol. xcv, p. 982.*)

SECTION ON PEDIATRICS.

First Day, Tuesday, May 6.

DR. FRANK VANDER BOGERT OF SCHENECTADY IN THE CHAIR.

Adenoids, Chronic Conjunctivitis, and Photophobia.—A Case and Cure.—Dr. GEORGE DOW SCOTT of New York read this paper, in which he emphasized the fact that pediatrics embraced many specialties and that the pediatrician should be able to remove tonsils and adenoids successfully, treat nasal orifices, and perform paracentesis of the ear drum. The patient whose history he reported was that of a girl 6 years of age, who first came under his care in May, 1917, presenting a photophobia which was pitiful to see. Twelve months before she began to suffer with severe lacrymation, nasal discharge, and photophobia. During this time she had had medical relief for a few days, but never a cure. In January, 1917, she had intense radiating pain in both ears and a profuse discharge from both aural canals, severe headache and fever. At least a dozen ophthalmologists and aurists had been consulted, one of whom removed her adenoids and tonsils, but this was not properly done and the symptoms became worse. Others had treated the condition with atropine and argyrol, and some did not seem to know just what to do. The conjunctiva showed marked hyperemia and abundant secretion and the cornea was slightly infiltrated. There was a thick mucoid discharge from the lids, but no pus was visible. There were slight radiating head pains. The tonsils were hypertrophied and there was a slight watery grayish discharge from the nostrils. The middle and inferior turbinates were congested and hyperemic. The speaker did a thorough removal of the tonsils and lymphoid tissue in the oropharnyx and in the fossa of Rosenmüller and epipharynx. Ten days later the child returned to the office with only a slight photophobia and diminished catarrhal symptoms. Since that time no further symptoms had arisen. The writer described the intimate anatomical relations between the sphenoid and post ethmoid cells and the lachrymal cavities, and also the arterial anastomesis, which was so important and vital. The bacteriological findings in this case were uncertain, but they had presumably found in the conjunctival secretion streptococci, staphylococci, and the pneumococci of Fraenkel. On the other hand, Magitot mentioned observations made in the trenches in Europe showing that out of 100 cases of keratoconjunctivitis nasal lesions were found in 95 per cent., and what was surprising was that bacteriologically the conjunctival secretions were mostly negative. In most cases nasal conditions did not end in eye infections and consequently there must be in such cases not only infection from without, but something from within. Adenoids, though seldom diseased, were often the predisposing cause of that train of symptoms and conditions ending in conjunctivitis and photophobia as well as many other conditions and the pediatrician should know more about them. The cornea, strange to say, was rarely affected directly by disease of the nasal cavities. The moral was that experience, thoroughness, and faith in one's self could often surmount obstinate difficulties.

Dr. JOHN O'BRIEN of Schenectady expressed the opinion that Dr. Scott's experience was indeed unique. This type of case was common enough to be familiar to most active practitioners. It was easy to miss the significance of recurring attacks of conjunctivitis and keratitis in relation to their causation and equally easy to form hasty deductions from a small number of cases. It was certainly not within his good fortune to see inflammatory reactions in the eye that were indubitably due to adenoids. But this, like most things, was possible. Adenoid tissue in young children was seldom pathological, so that whatever damage it did to either eye or ear was altogether mechanical by obstruction to the nasopharyngeal drainage. The same was true of hypertrophied tonsils. It was because of the obstruction that the early removal of these structures was always advisable. In all eye inflammations of sudden onset it was wise to look for foreign bodies on the surface of the eyelids, because they were the most common cause of these inflammations. The cornea should also be carefully searched for abrasions and ulcers, especially was the depth of the latter to be noted, for superficial ones did little harm. The location was also important, for the further an ulcer was from limbus the poorer its blood supply and the greater the danger of corneal perforation. The vision of an eye would not be limited in the least by an opacity if not in the papillary area, while a minute one in the center of the cornea might seriously impair the vision. One should observe carefully the reaction of the pupil to light. These observations would inform one as to whether iritis was present. Pain in the brow, especially at night, over the affected eye nearly always indicated the latter. The nose and throat should also be inspected. Had this been done early in this case the causative factor would have been detected and removed with a happy ending. Dr. Scott, by an oversight, had not told them of the result of the pathological examination of the tonsils. His paper was important in directing attention to the importance of prompt cure in the eye inflammations of children. Another condition that might be mentioned in this connection was phlyencula of the cornea and conjunctivitis so prevalent among children. One could give prompt relief in this condition by the exhibition of tuberculin in addition to the usual local treatment. The dosage must be minute, one drop of old tuberculin to an ounce of normal salt solution. Eight drops of this was put in one-half ounce of normal salt solution. This should be made fresh every month. One began by giving an injection of three minims and increasing the dose by one minim at each injection. Three or four treatments usually sufficed to bring about a cure, and there was seldom a recurrence. These phlyencule resulted in corneal opacities if not cared for, and as the pediatrician saw these cases early and their treatment was well within his sphere he should be able to treat them.

Dr. CARL G. LEO-WOLF of Buffalo said he took issue with Dr. O'Brien's advice with reference to the removal of tonsils and adenoids. He saw cases almost daily in which the tonsils and adenoids had been removed, much to the reproach of the pediatrist. He protested against the indiscriminate removal of tonsils and adenoids. The adenoids would return because the condition that had caused them to enlarge in the first place still persisted after their removal. Improper diet was often a factor in maintaining the condition that was responsible for their recurrence.

Dr. J. SCHILLER of Amsterdam said he examined as many as 5,000 young children in primary schools and kindergartens every year and found tonsils and adenoids removed from many children in whom it was difficult to find out why they had been removed. He agreed with Dr. Leo-Wolf that in many children in whom the tonsils appeared to be large during the early years they would be of normal size by the time the child reached the age of fourteen or fifteen years.

Dr. GODFREY R. PISEK of New York City said he did not think they ought to stop at this point. The pendulum had swung too far one way for a time and too many tonsils and adenoids were removed and now it was swinging too far in the other direction. They should recognize that there were certain types of cases in which the tonsils and adenoids ought to be removed, either because of mechanical causes or of disease. Many cases were reported in which the condition of the tonsils and adenoids was not correlated with the child's general condition. There were certain large tonsils that would undergo degeneration and disappear and, on the other hand, there were others in which this would not take place. Each case must be made a subject for investigation before undertaking removal.

Dr. SIDNEY V. HAAS of New York thought it was

quite fair to make a plea similar to that of Dr. Pisek in reference to paracentesis. For a while early paracentesis was popular, but he thought it was not only not wise to insist upon early paracentesis, but that it was frequently wise to delay the procedure. Ten or twelve years ago he had had a mother and two children, all of whom had an infection which produced a double otitis and he incised all the ear drums early and all six mastoids required operation. He had now learned to wait and found to his surprise that when he followed this plan the mastoids did not require operation, and these cases went on to perfect recovery. In cases of otitis media he gave urotropin, 20 grains a day, where it could be borne well, and hot water irrigations for pain, and waited two or three days before opening the drum and frequently an operation was then unnecessary.

Dr. T. Wood Clarke of Utica said he had seen much otitis this year and his rule was to watch the ears closely and to give urotropin and applications of alcohol and glycerin, and to wait for a bulging drum before doing a paracentesis. There were cases of bronchopneumonia in which it was sometimes difficult to find the lesion and in such cases it was a good idea to get rid of the wax and examine the ear, when one would sometimes find a red and inflamed drum. He had had 15 cases of otitis media during January, and the plea he wished to make was that every man handling children should make a routine practice of examining the ears in every case. Many cases of vomiting, colic, and supposed teething were found to be due to ear trouble.

Dr. F. H. Pierson of Syracuse said he also wanted to emphasize the importance of making a routine examination of all ears in children. This was a good practice, both in institutions and in private practice. He was sure he had seen more cases of otitis media in his own work this year than he had ever seen before during a similar period of time. One should always make this routine examination and especially if there was a temperature that could not be accounted for.

Dr. O'Brien of Syracuse said that, in speaking of the removal of the tonsils and adenoids, he did not mean the indiscriminate removal; he thought it was understood that experience and observation determined when tonsils and adenoids should be removed and when they should not. In his experience no diet had any influence on hypertrophied tonsils and adenoids. With reference to paracentesis, it did little good to open the ear drum merely by one slit. Good drainage should be provided. The same principles should be applied as were applied to surgery in other parts of the body.

The Atropine Treatment of Pylorospasm and Pyloric Stenosis.—Dr. Sidney Valentine Haas read this paper, in which he said that hypertrophic pyloric stenosis was probably only an advanced degree of pylorospasm, both being manifestations in the syndrome of hypertonia. The hypertonic infant was a definite clinical entity. It was characterized by hypertonicity of all the skeletal muscles, as shown by the ability to raise the head and grasp objects even in the early days of life, and by general spasticity. The hollow viscera showed increased activity of their smooth muscle fibers. This expressed itself in the form of spasm, involving practically every part of the digestive tube, and, depending on the region, presented the symptom of colic, visible peristalsis, vomiting, constipation or any combination of these. Accompanying these symptoms was marked psychic irritability, expressed by insomnia, general restlessness, and crying. The hypertonic infant belonged to the spasmophilic group and presented the symptoms of vagotonia. Its recognition was of importance in this, that while presenting symptoms in the main of disturbances of nutrition, food regulation alone did not correct the fault, whereas treatment by the drug atropine was followed by rapid subsidence of symptoms, the results being so prompt and regular as to constitute specific action. The tolerance for milk, which was usually low in these infants, was at once materially increased, so that a normal amount might be utilized—a condition quite opposed to that existing before the atropine was begun. The etiology was probably a disturbance in the physiological action of the vegetative nervous system. The vegetative nervous system was made up of two parts, the autonomic and the sympathetic; normally in balance, in this condition there was an overaction of the autonomic or vagotonia. This did not gainsay the occasional existence of true organic stenosis of the pylorus. Despite the brilliant results of many surgeons by the Rammstedt operation, in this condition an operation should be rarely required, and only performed after atropine had been given a trial. Atropine properly used had been regularly effective in producing a cure. At the present time the weight of authority would seem to indicate that hypertrophic pyloric stenosis and pylorospasm were two definite clinical entities. In favor of this view was the existence of a cartilaginous hard mass of the pylorus in cases of stenosis, and the persistence of this mass long after a cure had been obtained by operation or otherwise. Against this view was the experience of the last four years. All cases of pylorospasm, including four for whom operation had been advised, responded to treatment by atropine. A case of complete stenosis responded equally well. Ransahoff and Wooley held an autopsy on an infant at 7½ months which had had a Rammstedt operation at the age of ten weeks, when a cartilaginous hard mass existed. At the autopsy this was absent and the pylorus patulous. Ratchford stated that if the pylorus sphincter was so cut as to leave the orifice patulous and prevent muscular spasms of these fibers the pyloric tumor disappeared. Strauss, in a dissection of 65 tumors at operation, showed that the tumor was absolutely proportionate in size to the age of the infant, "which demonstrated that the tumor must be a progressive developmental affair." The absence of fault in the arrangementment of the normal histological elements of these tumors spoke loudly in favor of a functional creation. Rogers states that in fatigue the inhibitory impulses of the sympathetic system fail, and the vagus, then overacting, caused hypersecretion, hyperacidity, and hypermotility or pylorospasm. Among the arguments used against medical treatment was the sudden death, which not infrequently occurred. These were usually thymus deaths, and occurred in cases operated on as well as those medically treated. Atropine was the logical treatment in these cases owing to its paralyzing effects upon the vagus nerve endings. Certain facts must be borne in mind regarding atropine: (*a*) The inconstancy in value resembling digitalis in this respect; (*b*) Its rapid deterioration; (*c*) It must be used in sufficient dosage to be effective. A common dose of atropine for an infant of this type from a few weeks to a few months of age was gr. 1/50 to 1/25 in 24 hours, with an extreme of gr. 1/16 divided among the day's feedings, a 1:1,000 solution being used, beginning with one drop and increasing rapidly until effective. The most frequent toxic symptoms were flushing, midriasis, dryness, which disappeared promptly when the drug was withheld. There was no danger even when such symptoms present themselves.

Dr. Baehr of New York said he was of the opinion that Dr. Haas had offered something of value for that class of cases which was under discussion. He felt that it would be a help in these cases in which there was not a palpable tumor and in which one felt that if vomiting could be stopped the child might be carried through. There was, however, a large number of cases that would get well on almost any treatment. He had had one case which showed an intolerance to atropine. By beginning with one three-thousandth of a grain he was able finally to give one-fortieth and two weeks later one-twentieth of a grain. He also cited a case in which atropine gave no relief after having been used for two or three months. He thought that might have been due to a condition of the nervous system dependent upon calcium metabolism. Possibly it could be explained by thyroid deficiency. Thyroid extract favored calcium retention and was often an adjunct in this type of cases.

Dr. Elias Bartley of Brooklyn said he had had little experience with atropine in the treatment of pylorospasm, but he had used tincture of belladonna pushed to the physiological limits. He cited a case of an infant suffering from pyloric stenosis, which had been narcotized with opium when he was called to see it. He used injections of belladonna and whey per rectum and the child finally recovered. Since that time he had treated a number of cases along similar lines with very satisfactory results. He described observations made on

four cases which confirmed Dr. Haas's statement that the longer pylorospasm persisted the thicker the wall of the pylorus became. He thought that often a stenosis was due to edema of the pyloric walls following spasm or interference with the circulation rather than to a permanent thickening, and in such cases the belladonna or atropine treatment often effected a cure.

Dr. T. Wood Clarke of Utica referred to studies he had made some years ago in reference to the chemistry of the gastric secretions in cases of pylorospasm and stenosis which indicated that there was a hyperacidity. Since that time he had been cutting out the fats in these cases and feeding concentrated skimmed milk and under this régimé 70 per cent. of the cases recovered without operation. He asked Dr. Haas if he thought that possibly the atropine lessened the acidity of the gastric contents and in this was produced a beneficial result.

Dr. Isadore H. Goldberg of New York also reported several cases of pyloric obstruction cured by atropine.

Dr. Godfrey R. Pisek of New York City said he was sure Dr. Haas did not wish them to carry away the idea that every case of vomiting should be given atropine. He thought a distinction should be made between two types of cases, one the hypertonic and the other where there was a pyloric obstruction due to spasm or tumor producing a stenosis. The hypertonic infant was unquestionably helped by atropine. He had at first taken issue with Dr. Haas on this subject, but he had learned that if one used the large doses of atropine, as Dr. Haas described, it gave good results. In cases of true pyloric stenosis he was more inclined to advise early operation now than he was a few years ago.

Dr. Thomas S. Southworth of New York City said he had used atropine in these cases both before and after he had heard Dr. Haas's views on the subject, but he claimed no priority to the treatment, as Dr. Haas had developed the use of the large doses. He felt that atropine was a help in various types of vomiting that could not be attributed to defects in feeding.

Dr. Frank J. Williams of Albany reported a case of a child that showed intolerance for atropine when a dose of one drop of a 1:1,000 solution was administered.

Dr. Haas said he felt from what had been said that his deductions were along correct lines. He was particularly interested in hearing one of the speakers state that he had found the atropine treatment good for enuresis. He called attention to the fact that one might have a vagotonia which did not involve the skeletal system.

Colon Bacillus Pyonephrosis in Infancy.—Dr. Frank J. Williams of Albany presented this paper, which gave a clinical report with postmortem findings of a case of colon bacillus pyonephrosis in a two weeks' old male infant. There was sudden onset of symptoms at the age of two weeks and death occurred one week later from bacillus coli septicemia. The most prominent symptoms were marked abdominal distention, severe pain in the abdomen, and frequent loos green stools. The urine showed albumin and a large amount of pus. The postmortem examination revealed two abscesses in the left kidney and diffuse nephritis in both kidneys. The pelvic portions showed comparatively slight involvement. The mucosa of the entire urinary tract—ureters, bladder, and urethra—was involved in the inflammatory process, but the infection is looked up as descending via the lymphatic channels rather than ascending. Pus from the kidney yielded *B. coli* in pure culture. This case gave evidence of high pathogenicity on the part of the colon bacillus for the kidney substance in young infants in whom the activities of this organism were less inclined to be limited to the pelvic portion. It appeared from the cases reported in the literature that this infection claimed a much higher mortality among the very young than was the case in older children, and also that the generally recognized preponderance of female cases did not obtain in the very young.

Dr. T. Wood Clarke took exception to the statement that pyelitis was a common well known disease. He said it was very common, but it was not so well known. Many general practitioners did not make a routine examination of the urine in children and hence many cases of pyelitis were overlooked. Dr. Clarke related a number of such instances coming under his observations and emphasized the importance of a routine examination of the urine in children.

Dr. Godfrey R. Pisek said Dr. Williams's case was one of pyelonephritis and not of pyelitis. Cases of pyelitis were those in which the colon bacillus was merely on the surface of the pelvis of the kidney and did not permeate into the kidney; when they did permeate deeply into the kidney the result was a pyelonephritis, and it was the latter cases that were dangerous and occasionally fatal. These cases might be taken for cases of tuberculosis. One should make the functional test and find the specific gravity of the urine.

Dr. L. V. Waldron of Yonkers said he wished to confirm what Dr. Clarke had said in reference to pyelitis in children being overlooked by the general practitioner. The condition was usually treated by the general practitioner as tuberculosis or malaria.

Dr. Elias Bartley of Brooklyn spoke of the routes by which the colon bacilli might gain access to the kidney and called attention to the possibility that masturbation might be a means of causing the infection. He related a case in which he thought the infection had occurred in this way.

Dr. George Dow Scott of New York asked if there was such a thing as a true colon bacillus infection and if the infection was not a mixed one.

Dr. De Witt H. Sherman of Buffalo said his experience was at variance with that of several others who had spoken. Pyelitis was at the present time a very popular diagnosis in Buffalo. He recalled several instances in which conditions which were not pyelitis at all were classified under that diagnosis.

Dr. I. H. Goldberg of New York spoke of the difficulty of getting specimens of urine in young children and stated that a specimen could be obtained by placing the finger in the rectum and exerting pressure on the bladder.

Dr. Clarke said that a cleaner way was to watch the child just as it was waking up and massage the abdomen.

Dr. Williams said that no culture of the blood was made to find out whether there were colon bacilli present. A smear had been taken from the penis and yielded a pure culture.

Problems of Weaning.—Dr. TenEyck Elmendorf of New York presented this communication, in which he handled his subject from the standpoint of the general practitioner rather than that of the specialist in children's diseases. For convenience he divided weaning cases into two general classes: first, those that were unnecessary, including those that should have been unnecessary, and, secondly, those cases which must be weaned. In the first class were the lazy mothers who nursed irregularly and the habitual overeaters, whose milk balance was deranged by improper diet and who would not correct it; occasionally an appeal to the father would help in these cases. There were those who for business, social, or even cosmetic reasons would not nurse. With the business woman it might be possible to continue morning and evening nursing while the milk lasted. Then there was the highly nervous woman who took too much neighborly advice as to the diet and management of the child. In this latter class were also the women whose milk supply had taken a long time to become established, and who had been told by their physicians that their milk was no good before it had passed the colostrum stage; no analysis had been made and the child had been fed on some convenient prepared mixture as early as the second or third day. It was seldom possible to reestablish the milk secretion in these cases, as the mother was usually in poor condition after a difficult labor, or the breasts had been too long unused when the physician saw them. There was the woman whose menstrual period returned early and who had weaned abruptly without advice; and there were mothers whose breasts were painful and nipples tender who were afraid to nurse, and there were women with caked breasts with whom very little could be done, as the work should have been done before. There were some mothers whose milk was so abnormal that it could not be corrected. There were the high sugars with little else, the high fats which could not be reduced without drying up the supply, and the low fats. These two

latter might be helped by supplementary feedings. The worst of all were the samples, which were normal on chemical analysis and yet disagreed with the child. Here one might find that the nipple was at fault, or the position in which the child was held, or the conditions under which it was nursed, but as a rule these children did better on the bottle. The writer discussed the problem of finding a substitute for breast milk, and stated that he preferred fresh cow's milk (not pasteurized or boiled) for a steady diet, but found empirically that it was wiser to begin with pasteurized or even boiled milk, especially in the summer months. In training mothers to follow instructions they had the greatest problem of all, because in this one had to contend with the opinions and prejudices of the relatives. In the choice and hygiene of bottles and nipples the physician's difficulties became extreme. The size and shape of the nipple were important, some liking the large imitation breastlike nipple, while others seemed to be caught by color, be it red, white, or black; others by taste; this applied usually when the mother had burned a hole and had not washed out the burnt taste. The hole in the nipple might be too large and on this account be the cause of vomiting. The type of bottle was also of importance. The long round bottles were preferable. In the matter of heating bottles the writer had been surprised at the various methods of procedure. Some had boiled the bottle empty and then put in the ice cold food, with resulting indigestion and too many cracked bottles. Others had tried to heat the bottles directly over the flame most unsuccessfully. One should caution the new mother against using a vacuum bottle to keep milk hot over long periods of time, as milk kept warm too long was apt to disagree. In the preparation of food in which diluent was necessary it was well to be sure that there was no confusion in regard to the measurements; this was necessary, since teaspoons and tablespoons varied much in size. Mistakes were also made in the preparation of gruels used as dilutions, and the mother should be carefully instructed as to the methods of preparation of the particular cereal gruel that was prescribed. Many mistakes were made by the average everyday women, not through stupidity, but through unfamiliarity with the subject and a desire to follow most carefully directions she did not understand. From examinations of the nurses in training in our hospitals after lectures by dietitians and physicians, one found a like confused idea of infant food preparation. In giving instruction to mothers one must repeat and repeat again and sometimes in different words to get the results desired. After discussing many of the details of artificial feeding the writer concluded that their problems in weaning did not end with the selection of a formula, but rather began there.

Dr. SOUTHWORTH emphasized the importance of not abandoning breast feeding if it was possible to continue it, and said that the child that did not thrive on breast milk was usually a poor subject for artificial feeding. The physician should encourage the mother to take an optimistic attitude, as this was often an important factor in enabling her mother to nurse her infant. Even a few ounces of breast milk added to other nourishment was often life saving. Even a high fat content in the mother's milk did not create a hopeless situation, as a little lime water or bicarbonate of soda could be given before nursing the baby. Usually a high fat content of the mother's milk was only a temporary condition during the early period of lactation. A mucoid, green or greenish yellow stool in an infant that was nursing was not always evidence that the mother's milk did not agree with the child but might be evidence simply of insufficient food.

Dr. J. A. CARD of Poughkeepsie related a case in which the high fat content of the mother's milk was not a temporary affair, but persisted.

Second Day, Wednesday, May 7.

This was a joint meeting of the Section on Pediatrics with the Section on Public Health, Hygiene, and Sanitation.

Child Welfare Work Abroad During the War.—Dr. CLIFFORD G. GRULEE of Chicago delivered this address by invitation. He first described the organization of the American Red Cross and stated that he was connected with the Bureau of Children's Diseases. He explained that this bureau differed from that of the Bureau of Tuberculosis, which was organized in conjunction with the Rockefeller Foundation and planned its work for a period of ten years. The children's bureau was organized with the idea of giving immediate relief. He was connected with the work in and about Lyons and the work done there was fairly representative of the work done by this bureau throughout France. The population of the city of Lyons was 500,000 before the war, while the war time population was one million, so that they had to deal with all conditions incident to overcrowding. The work was divided into two classes, that of giving direct aid and educational work. While there were in France many organizations for giving aid to children and instruction to young mothers, there was an intense rivalry between different agencies and little cooperation. The American Red Cross in its work endeavored to enlist the cooperation of these local agencies and to subsidize them. The educational program consisted in three main activities, namely: (1) an educational exposition which lasted three weeks; (2) playground work, not only among the children, but in giving instruction in that kind of work to school teacher, for the children of France did not know much about cooperative playing, and (3) a course of training for school and visiting nurses. Both the trained nurse and the visiting nurse were unknown quantities in France. In the group of hospital and convalescent homes under his charge, having 1,100 beds, the nursing staff included only 11 trained nurses. The children coming under their care were of several classes. There were the refugee children that came around through Switzerland and through Avian, those from back of the French lines, and those from Paris. It was perhaps not realized in this country that in May, 1918, the French people were evacuating Paris, all banking securities had been removed from the city, the Red Cross people were packed and ready to start for other points, and all the children were being sent away. In addition to the refugee children, there were the children of the munition workers that had flocked to Lyons, and then the children that ordinarily belonged in the city. On March 1, 1918, the American Red Cross established a dispensary in Lyons and by May 1 were seeing 50 patients a day, and then soon they were seeing 87 or 88 and had to start another dispensary. Dr. Grulee gave a lantern slide and motion picture exhibition showing the various institutions under his direction and described the difficulties that were encountered in getting them started. He spoke particularly of the work done by the dentists, who was one of their staff, and stated that the bad condition of the French children's teeth could not be exaggerated. At the exposition the dentist's booth where he cleaned teeth was the most popular of the exhibits. He stated that the enthusiasm with which the propaganda for the care of children was received by the French people was most remarkable. This work done by the Red Cross did far more than relieve need and give medical attention to the civilian population, it strengthened the morale of the people and that of the French army, for the men fought better when they felt that their families were being cared for in their absence.

Child Welfare Work in Massachusetts.—Dr. RICHARD MASON SMITH, of Boston, made this address in which he stated that "Child Welfare work in Massachusetts had been done by private organizations for many years and by the State Department of Health since its reorganization. Due to the renewed interest in child welfare brought about by the war, a Child Conservation Committee was appointed by Dr. Allan J. McLaughlin, the Commissioner of Health, on May 26, 1917. The work of the Committee was supported by the Red Cross, by a special grant from the Governor and by funds of the State Department of Health. Eight nurses were employed for the first year to make a survey of the State. Local committees on child welfare were organized. In many communities the public officials or the private organizations were urged to increase or to introduce child welfare work. At town meetings appropriations were made for public health nurses. A considerable amount of literature was prepared for general distribution. Nearly $100,000

has been raised during the last two years for child welfare as a direct result of the activities of the Committee. The Committee was now an advisory body to the Division of Hygiene. It was working on plans to incorporate the enthusiasm, which had been aroused during the last two years, into permanent public health organization in the State.

Child Welfare Work in New York State.—Dr. H. F. SENFTNER, in the absence of Dr. Henry L. K. Shaw, described the child welfare work being done in New York State, exclusive of that done in New York City. They had adopted some of the methods which Dr. Smith had described. In the beginning they had followed the work done in New York City by Dr. S. Josephine Baker who was the pioneer in child welfare work in New York State. In 1908, New York City established its first Division of Child Hygiene in the Department of Health and in 1914 they had organized a similar bureau in the State Department of Health. The work as it had now developed aimed primarily to educate the mother, both before and after the birth of the child. An attempt had been made to reach every existing agencies engaged in this work and secure cooperation with the State Department of Health. They had tried to do this through the Woman's Council of National Defense, through which they had linked up the small agencies. They had sought the cooperation of the mayors, chairmen of common councils, local boards of health, chambers of commerce, supervisors of schools, federated women's clubs, mothers' clubs, consumers leagues, etc. With the cooperation of these agencies milk stations and prenatal clinics had been started in various localities and trained visiting nurses had been employed by a number of communities. The work had been carried out through exhibits, lectures, baby contests, posters, and literature. The supervision of school children was under the State Department of Education and the inspection of day nurseries was under another State Department. In 300 municipalities 114 lectures were delivered by some physician connected with the State Department of Health during 1918. In 55 localities there were 109 little mothers' leagues. Teaching these girls between the ages of 10 and 14 years the care of a baby and the general rules of hygiene was a very important feature of child welfare work and one that would have a far reaching influence. They were not taught a hodgepodge of medical lore but were taught to care for a healthy baby. The infant mortality rate had been lowered from 120 per thousand living births in 1913 to 94 in 1916; the rate was a little higher in 1918 owing to the epidemic of influenza. The main aim of the work was educational and not the treatment of disease. The work was growing rapidly as was evidenced by the increase in the number of milk stations in communities of all kinds and by the increased popularity of the stations as sources of advice to mothers. The getting of nurses for public health work was a matter of vital importance. Such a nurse must possess tact and perseverance and she must be able to answer the questions asked by the mothers. She must be able to interview mothers, arrange for lectures, give practical demonstrations, instruct the mothers in their own homes, and follow up the children which the physician said needed attention. She should receive not less than $100 a month. The Division of Child Hygiene had been largely instrumental in securing such nurses for various municipalities. Another rather unique feature of the work in New York State was the establishment of Sunshine Villa, a summer camp for children whose parents would otherwise not be able to get them out of the city. the conditions of this camp were ideal and it served well for a model for others of its kind. They had a booklet which they sent to newly married women throughout the State, getting the names from the marriage license lists, and they had evidence that they were getting results by this procedure from the letters that were received.

Dr. F. W. SEARS, of Syracuse, said he was particularly impressed by what Dr. Grulee had said in regard to the division of their work into relief and educational work. Their work in civilian life should be educational. The real cause of poverty and illness was lack of knowledge to spend what was earned properly. It was the function of public health work to protect families from illness and to protect babies from illness, and if the knowledge that their families were well was a factor in sustaining the morale of the fighting men it was equally a factor in increasing the efficiency of the workingman. There was nothing that so unfitted a man for his work as having a sick child at home. Public health work should be educational and the charity side should be eliminated. Sick children whose parents were in poor circumstances should be cared for in hospitals and it should be more emphatically stressed that the function of public health workers was to keep babies well. The infant welfare exhibit was a powerful factor in reducing infant mortality. The infant mortality in Syracuse was 122 per thousand living births but through an exhibit and literature it had been reduced to 98. Dr. Sears also emphasized the importance of recreation parks and of the necessity of educating municipalities to a recognition of their value. He told of the good work that a visiting nurse was doing in an Indian community where she had to make her visits on horseback to illustrate how difficulties in rural communities might be overcome. The ordinary training given to a trained nurse in hospitals in the care of children did not fit her for this work—she needed a special kind of training. In spreading health propaganda in a rural community a little ingenuity often served to get people together and get them interested. In one rural community when the local health officer had arranged for a lecture, he found on reaching the hall where he was to speak a notice stating that the lecture was to be on "The Rearing of Children and the Raising of Calves." Fortunately for him early experience on a farm enabled him to fulfill the second part of the contract. The notice served to bring an audience and as a result they were able to arouse interest in child welfare work in that community.

Dr. THOMAS S. SOUTHWORTH, after paying a tribute to the speakers for the excellent work that had reported, expressed the opinion that the plan of divorcing preventive work from the treatment of disease was correct. He said he was very glad to hear that child welfare work was being extended to rural communities and he felt sure that if the optimism expressed by the last speaker were general it would carry with it success in this work.

Dr. WILLIAM A. HOWE, of Albany, told of the early history of the Division of Child Hygiene in New York State, and said that at the time the division was organized 25,000 babies under one year of age were dying annually, this had been reduced to 10,000 in five years. It was a great satisfaction to direct the care of babies so that they were started right during the pre-school period. He felt that they should have a system of supervision of health that began before birth, extended through the primary, grammar, and high school, and on through life. Dr. Howe also made a plea for the coordination of public health work done by the Department of Health and that done by the Department of Education.

Dr. L. V. WALDRON, of Yonkers, related his experience in child welfare work in Yonkers where they had reduced their infant mortality rate from 122 in 1912 to 114 the following year and in 1917 to 84.2, tying Rochester. In Yonkers they were now inspecting midwives and baby boarding houses. Their infant mortality rate thus far this year was only 69. They had been able to convince the Board of Education of the value of the little mothers' work and a course for little mothers was scheduled to be taught in the Domestic Science Department of the Public Schools. The work among little mothers was one that paid.

Dr. PEARSON, of Schenectady, said that Dr. Grulee had said that the child welfare work at Lyons was fairly representative of that work in France, and he would like to supplement that statement by saying that it was a model for work of that character anywhere. He had had very little experience in this work in France because he was transferred to general hospital work. He had found, however, that the average French mother was willing to cooperate with the doctor and nurse if she understood why a thing was

done. Dr. Pearson described his experience in connection with the care of refugee children in châteaux near Versailles.

Dr. WALTER A. SCOTT, of Niagara, spoke of the difficulty of reaching people who spoke a foreign tongue and advocated the publication of advice in the care of children in other languages. He believed that the medical school inspector should also be health officer. He related his experience in starting little mothers' leagues and felt very enthusiastic in regard to the value of this work. Through the little mothers' work the girls learned to value the advice given and would come to the health center or baby station for advice when they were "big mothers."

Dr. F. W. BOCK also made a plea advocating the unifying of child welfare work under the authority of one department and believed that for this purpose the Health Department was better than the Department of Education.

Dr. T. WOOD CLARKE told of the experience with infant welfare work in Utica which had resulted in a reduction of the infant mortality rate from 158, seven years ago, to 101 last year. As a means of getting the doctors to attend to the work regularly at the milk stations, they had adopted the plan of deducting a certain sum from their monthly salaries when they were absent and found that, small as this sum was, it had made their attendance much more prompt and regular. He also called attention to the change in the Child Labor laws which forbid the employment of children under 14 years of age. This had operated to keep a great many children in the city that might otherwise get into the country to pick vegetables in the summer time. He thought there ought to be some way to have the law modified so that children could be employed in light work out of doors.

Milk Powder.—Dr. A. CLIFFORD MERCER of Syracuse presented this paper in which he described the cylindrical and spraying processes of manufacturing powdered milk. He exhibited specimens of the milk made by both processes and tables showing the composition. The milk made from powder manufactured by the spraying process resembled a little more closely fresh milk. He described his very satisfactory experience with milk powder in infant feeding. The milk made by dissolving this powder in water had much the same taste as fresh milk, contained enzymes and vitamines, and the fat was homogenized. It cost about sixteen cents a quart. Modifications cost about 33 cents a quart. Dr. Mercer gave a motion picture exhibition showing the entire process by which the milk powder was manufactured in Syracuse.

Dr. ROGER H. DENNETT, of New York City, said he thought milk powder had come to stay though he had had no experience with the particular product which Dr. Mercer had described. He had, however, had experience with that made by other processes. He thought there were certain indications for the use of dry milk and that one of these was in premature babies when breast milk was not available. He had also found it useful in some cases of vomiting, and in pylorospasm. Dr. Hess had shown that dry milk was antiscorbutic; this was probably due to the fact that it was dried while it was fresh. It seemed that a baby utilized more of the milk made from powder than it did of fresh milk, and required ten or fifteen calories per pound less when fed on powdered milk.

Dr. L. T. LE WALD said he would like to hear something about infantile scurvy as he understood that it was quite prevalent in New York at the present time.

Dr. H. DEWITT SHERMAN, of Buffalo, thought the paper was a little unusual for a Pediatric Section and hoped the deduction would not be made that milk powder was a panacea suitable for all cases. He did not feel quite convinced that the vitamines were present. This milk powder might be useful in an emergency just as other milk preparations were, but he would not want to give the impression that it could be used in every case with safety.

Dr. THOMAS S. SOUTHWORTH said that Dr. Sherman's position was well taken,—that in presenting any new type of infant feeding it was always necessary to add the addenda that it was only one of many methods and that it was not a panacea. The question that came up most prominently in reference to such a milk powder was that it was available in localities where fresh milk could not be obtained or in warm climates where fresh milk could not be kept. Dried milk had been a great advantage in France during the war. It was not absolutely necessary that a dried milk should have vitamines as these could be supplied by orange juice.

Dr. CLIFFORD GRULEE, of Chicago, said he did not see how one could have sufficient freedom in adapting a formula to an individual case with the powdered milk, but he could readily see its advantage in such conditions as had existed in France. He did not see that it possessed any particular advantage in communities where a supply of fresh milk was available.

Dr. MERCER, in closing, said he himself used very little milk powder; most of his babies were fed on certified milk, but he thought it would be interesting to have a ventilation of the milk powder question. The 3½ per cent. powder which was shown was nothing but whole milk and could be modified just as whole milk was modified. As to the vitamines, Dr. McCallum's article on this subject was in the May number of *Biology and Chemistry*. One could make junket of milk from the powder or it could be churned.

Obstipation in Children.—Dr. I. H. GOLDBERGER of New York City, read this paper in which he said that idea he wished to convey might be summarized in the words of Dr. Leon T. Le Wald, who in the course of their study to determine the possible causes of obstinate constipation in infants and young children said: "The pediatrist has no more right to treat obstinate constipation without the aid of the roentgen ray, than the surgeon has to treat a fracture without similar aid." In this age it was hardly possible to believe that the surgeon would attempt to set a fracture without the aid of the radiograph, yet case after case of chronic constipation of unknown cause was treated without anything more to guide us than a hurriedly obtained history that the child had difficulty in having daily evacuations, or that the stool was hard and dry, or the quantity passed was insufficient. The indiscriminate and long continued use of catharties of all descriptions without giving permanent relief was evidence that the causes of constipation were seldom discovered. Every case of chronic constipation should be looked upon as a complex problem to be studied thoroughly, with a proper appreciation of the anatomy and physiology of the gastrointestinal tract, and supported by clinical evidence and by good roentgenograms, before deciding upon a diagnosis. When a pediatrist started to treat a case of obstinate constipation he should first determine the region of the bowel in which the stasis occurred, namely, in the distal colon and rectum or in the proximal colon. Secondly, he had to decide whether or not he was dealing with a case of obstinate constipation of the congenital or the acquired type. Under the congenital causes of constipation the writer considered those due to anatomical peculiarities in structure and arrangement of the gastrointestinal tract, such as elongated colons, dilated colons, ptosis of the colon and stomach, dilated cecum, pyloric obstruction, pylorospasm, and various angulations and kinks. Of the acquired causes there were three distinct types, the atonic, spastic, and obstructive. Viewed from the standpoint of type and cause, chronic constipation was not the simple disturbance we originally thought it to be. Cathartics did not solve the problem. The histories of seven cases showing various anatomical anomalies were reported which the writer stated verified the findings of Dr. Kerley who in a radiographic study of 57 cases whose gastric disorders proved difficult to solve found in his gastric series dilatation, ptosis, pylorospasm, pyloric obstruction and hypertonicity. In his intestinal group he discovered dilatation of the colon, ptosis of the colon, adhesions, sacculations of the cecum, signoid, etc. In discussing the treatment of these cases, it was shown that the majority of the cases of chronic constipation were due to spastic and obstructive conditions. The primary state of the bowel in constipation was spastic, but through the long continued use of irritating and stimulating cathartics, the spasticity was followed by a state of atony. It seemed therefore that the patient required the use of anti-spasmodic drugs, and not irritants like calomel, cascara, castor oil, phenolphthalein.

magnesia, etc. If the seat of the constipation was in the dilated portion of the colon, it seemed unreasonable to administer laxatives which would irritate the first twenty-five feet of bowel in order to evacuate the last fifteen or twenty inches of colon. Local treatment was more conservative and effective. In every case in which there was a history of constipation that dated back to birth, a complete roentgen examination of the gastric and intestinal canal should be made. In the cases due to elongated and dilated colon, the first thing to do was to withdraw all laxatives for the period of treatment, usually from two to three months. The next step was to prescribe an adequate diet, special emphasis being placed upon food which would leave plenty of residue. Plenty of fruits both raw and cooked and green vegetables were appropriate. Potatoes should be omitted except for baked potato, when the inner portion should be removed and the portion nearest the skin eaten or the jacket might be eaten. Whenever possible the water in which the vegetable had been cooked should be served with the vegetable, since it contained the mineral salts, and was excellent in improving the general tone of the child. Cereals should be of the whole grained type, such as wheatena, Indian corn meal, brown rice, Irish or Scotch oatmeal. These should be taken with the addition of cream or butter and honey. Malted sugar might be substituted for honey for sweetening purposes. The fluid portion of the diet should consist of water, malted milk with water, small quantities of cream, buttermilk, etc. Difficulty was sometimes experienced in making these children eat. A few minims of tincture of nux vomica alone or in sherry a half hour before meals often did wonders. An abundance of outdoor exercise should be prescribed. The closest kind of cooperation on the part of the mother was imperative. Certain forms of exercise and abdominal massage were also to be recommended. At night the child was given an injection of olive or sweet oil, about three ounces instilled into the rectum by a tube introduced for about six inches. He should be encouraged to retain this over night and until after breakfast the following morning. In the series of cases reported this line of treatment had given perfectly satisfactory results.

Dr. Leon T. Le Wald said that this problem which Dr. Goldberger had brought up of trying to work back to a definite cause for constipation was one which should be given careful consideration. In hospitals it was a very easy matter to have an *x*-ray taken but it was much more difficult in private practice to convince people that this was necessary in cases of constipation. Dr. Le Wald showed a series of lantern slides of observations made at Bellevue and St. Luke's Hospitals which illustrated the various types of anomalies that might be found in the intestinal tract that gave rise to obstinate constipation. Anomalies were shown in all parts of the intestinal tract from the esophagus to the colon. In speaking of redundant colon in children he said that one did not feel justified in operating on these cases at the present time and the statement had been made that this condition might be outgrown. He did not believe it could be outgrown and felt that a redundant colon was always a potential source of trouble.

The Eruption of the Teeth and the Subsequent Development of the Jaw.—Dr. H. O. Brown, Superintendent of Infirmary, Rochester Dental Dispensary, presented this paper in which he stated that his work had shown the great need which the dental and medical professions had of each other. Dispensaries of the sort with which he was connected could only succeed when they had the whole-hearted support of the medical as well as the dental profession. There were several factors which hastened or retarded the eruption and consequently influenced the development of the jaw. The deciduous teeth were, taken as a whole, a mould put there for the purpose of holding the child's jaw in shape to receive the second set. Unless these teeth were interfered with in some way they would erupt normally, which was with the uppers biting slightly over the lowers, each tooth approximating the other and the whole forming an even curve from central on back to molar. Probably the greatest factor causing an irregular eruption of these teeth was the enlarged tonsil and adenoid. Mouth breathing through muscular attachment at the angle of the mouth caused an abnormal pressure on the side of the arch, thus narrowing the vault and causing the commencement of what was known as the "crow beak" mouth. Another factor influencing the deciduous teeth was thumb sucking. Contrary to the usual opinion the greatest amount of damage from thumb sucking was not upon the upper set but upon the lowers. Pacifiers and rubber nipples also tended to cause the same effect only not so pronounced. As the child approached the age of from five to seven years, a slight spacing of the teeth was noticed under normal conditions of development. This was nature's provision for the larger incoming teeth of the second set. If this spacing did not take place normally the orthodontist should be consulted, and the case taken in hand, as at this time it could be handled very easily and quickly by simply stimulating the proper development of the arch and providing the necessary room. If normal spacing had not taken place and there was a constriction of the arch, the incoming teeth were obliged to come in turned on themselves, because of being larger than the ones whose places they filled. Usually a lack of development in the upper cuspid region was responsible for this. Early extraction played a very important part in the irregular and premature eruption of the second teeth. Each tooth as it set normally in the jaw exerted a lateral pressure against the approximating teeth. It was this lateral pressure of one erupting tooth against the other that assisted so materially in the development of the jaw. If one were lost before its time the adjacent teeth were allowed to move forward or backward, as the case might be, thus narrowing the space needed by the incoming permanent tooth. It was impossible to give the exact date at which one tooth might be safely extracted. They seldom, however, extracted a first premolar before nine years and a second before eleven, while they tried to keep the cuspid in place until forced out by the incoming permanent cuspid, usually at about twelve years. Occasionally it became necessary to extract a deciduous tooth before its time, as in the case of badly broken down and infected tooth. Ordinarily a simple abscess on a first tooth did not indicate extraction as these responded very readily to treatment and could usually be saved if the dentist gave them proper attention. If a tooth refused to answer to treatment after a reasonable trial, it should be extracted rather than be allowed to remain and necrose the alveolus, as it was much better to have a sound irregular set than an even chalky one. If it became necessary to extract a tooth before its time, an orthodontic appliance should be placed on the adjacent teeth which would preserve the space until the second tooth had had time to erupt. The too long retention of the deciduous teeth would cause as much trouble as their too early removal. Sometimes one found sound premolars in place with no sign of bicuspids. In these cases it was very unwise to assume that because it was time they were lost that they should be extracted, for often the bicuspid had failed to form, in which a deciduous extraction meant a permanent space. It was not only the bicuspid that sometimes failed to form, but also the laterals, lower centrals, and cuspids, but he had never yet seen a case in which the upper centrals had failed to form. Premature extraction carried with it another danger. The follicle of the second tooth was formed within the grasp of the deciduous roots and to extract such a tooth before the absorption of these roots meant that the follicle of the second was removed with it, which of course meant a permanent space, allowing the rest of the permanent teeth to drift toward each other, throwing the chewing planes out of line so there would be only one or two cusps in contact with the opposing teeth. This meant improper mastication. Owing to the bell-like formation of the crowns in such teeth there were many spaces which afforded lodging places for particles of food so that pyorrhea was almost sure to show eventually in a mouth of this kind.

The Measure and Development of Nutrition in Childhood.—Dr. George M. Retan of Syracuse presented this communication in which he stated that during

the past year the state of nutrition of the American child had occupied a prominent place. A large amount of work in the correction of malnutrition had been done both in the schoolroom and the clinics. The results of this work demonstrated a new responsibility of the physician. These cases of malnutrition in children should be corrected, for malnutrition in children reduced their resisting power to infection and retarded their normal growth. The measure of nutrition was the best indication of a child's state of health. The first step in considering a nutrition problem was the adoption of a correct standard of measurement. There were five possible factors that could be used as a basis for measurement. These were age, weight, height, sex, and nationality. There were three relationships that should be considered: the relation of age to weight, the relation of age to height, and the relation of height to weight. The writer showed that the relation of height to weight was the correct standard Most scales of nutrition had been based on average weights. Inasmuch as 20 per cent. of all children had been found to be undernourished and but two per cent. had been found to be overnourished, the average of all children would not be the average of normally nourished children. Furthermore, this method would give a concrete number as the normal weight of a given child, but there could be no concrete number for the normal weight, since normal weight was variable and should be represented by a zone. The charts presented showed a scheme for determining the zones of normal nutrition, malnutrition, and over nutrition, as based on the relationship of weight to height. The facts of sex and nationality were considered and it was shown that a separate measurement for each sex was not necessary. It was also obvious that nationality played no rôle in the measure of nutrition when the nutritional standard was represented by zones based on the relation of weight to height. Malnutrition should be considered in the same light as actual disease. Its cause should be determined and remedied. The principal causes might be classified as: (1) physical defects, such as adenoids, hypertrophied tonsils, decayed teeth and eyestrain; (2) habits, as food habits, coffee, tea, alcohol, candy between meals, etc., lack of sufficient rest; (3) hygiene; (4) disease, as tuberculosis, syphilis, etc. These causes of malnutrition suggested the proper procedure to follow in their correction. The majority of all malnutrition cases were caused either by infected tonsils and adenoids or by faulty diet and sometimes by a combination of the two. Statistics were presented showing the effect of tonsillectomy on nutrition. A summary of the weights of 95 children who had had their tonsils removed for at least one year showed that 71.5 per cent. had gained more than the average yearly gain used as a basis for comparison. They had also made an investigation to determine the diet of 530 school children between the ages of five and twelve years. The data showed that nearly one-half of these children received insufficient food and that over one-half were in the habit of drinking coffee. This demonstrated the importance of considering diet in relation to any nutritional problem.

Dr. William B. Hanbidge, of Ogdensburg, said he thought the question of malnutrition in children was one of the most important questions before the American people today. The finding of the draft boards that over 40 per cent. of young men had physical defects and that a good many of these defects were related to the problem of nutrition had convinced physicians that we must have some mathematically accurate system of determining whether a child was being properly nourished and was growing normally. The pediatrists of America must impress the people with the necessity of giving attention to the proper nutrition of the child during his period of growth. In connection with the problem of proper nutrition there was also a psychic element. Frequently a child who did not eat well and grow well in the city under the stress and strain and excitement would show a wonderful change under a different environment or in a simple country life. Economic questions were also intimately bound up in the problem of proper nutrition for the growing child; these questions we did not know just how to handle at the present time. The pediatrician was to be congratulated on the splendid work he had done for the children of the country, a work that meant so much for coming generations and for the future of America.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 3, 1919.

The President, Dr. George David Stewart, in the Chair.

This meeting was held in cooperation with the Section on Medicine.

Dr. Stewart, in opening the meeting, explained that the motion pictures which were to have been exhibited by permission of the War Department had not arrived, and that it had been found necessary at the last moment to improvise a program varying somewhat from the printed announcement.

Motion Pictures in the Diagnosis of Tuberculosis.—Major Henry Farnum Stoll of Hartford, Conn., made this presentation. After expressing his appreciation of the honor conferred upon him in asking him to present motion pictures on the diagnosis of tuberculosis, he stated that the title of his presentation as given on the program was somewhat misleading. It might better have been "The Motion Picture as an Aid in Teaching the Diagnosis of Tuberculosis." The teaching possibilities of the motion picture had already been demonstrated in other lines of medicine. The method of teaching by means of the motion picture made possible the showing of the modern treatment of war wounds and burns and the remarkable collection of shell shock cases collected by this means would be of great value in years to come, when there would be no opportunity to get this kind of case. The animated drawing, or in "movie" parlance, the "animated cartoon," was an even more recent departure, the teaching possibilities of which were really very great. Those who had seen the demonstration of the way in which a hernia was caused, showing the peristalsis, the way in which the loop of gut went beneath the ligament and fascia and produced a hernia, or those who had seen the demonstration of how vertigo was caused, or how infection traveled up through the uterus, tubes and ovaries, and the pus gained access to the abdominal cavity, realized that the animated drawing could make an impression on the mind of the student that was more lasting than the most eloquent description. In performing an operation the surgeon's hand obscured the field so that one could not see what was being done, but with the animated drawings one could see every step in the procedure. Col. Owen had been foremost in developing the motion picture as a means of teaching in the Medical Department of the Army; it had also been used in the Army Medical School and at a number of officers' training camps. He very much regretted that the film that he had intended to show this evening had not arrived. He would, therefore, occupy his time by speaking on the subject of the "Diagnosis of Tuberculosis." They had tried to arrive at a standard for the diagnosis of tuberculosis in the Army, and to adopt certain standards for rejection and acceptance of recruits, and in doing this they thought it would be an advantage if certain principles underlying percussion, auscultation, and palpation could be put on the screen for the benefit of the men to be instructed. The film showed the method of inspection, palpation, and percussion, the results of strokes of different force, the motion of the alveolus in breathing, coughing, etc. Their experience had shown them that a number of cases that at first seemed to be tuberlosis later proved to be something else. Of the cases referred to them for diagnosis, some had suspicious signs and some suspicious symptoms, but they found that the majority of the cases did not have tuberculosis. They found many lower lobe lesions with persistent signs following pneumonia. Some of these had various adventitious sounds that simulated râles and others had abnormal sounds at the right apex. In these the *x*-ray often showed conditions other than tuberculosis. Again some cases that were thought to be incipient were found on *x*-ray examination to be advanced. Some cases showing few or no symptoms had definite lesions of both upper lobes

which led to the belief that frequently incipient cases were not attended with symptoms. The *x*-ray afforded very valuable aid in arriving at a diagnosis, but must be taken in connection with the physical symptoms and the laboratory findings. It was essential that all these methods be studied together. Peribronchial streptococcus lesions sometimes gave *x*-ray findings simulating tuberculosis and in differentiating these the complement fixation test might be of assistance. They had had some experience with this test of which his opinion might be expressed somewhat as follows: (1) With suspicious symptoms and physical signs that seemed suspicious, but not conclusive, a repeated negative complement fixation increased the probability of the condition not being tuberculosis. (2) But if under these same conditions the complement fixation test was repeatedly positive the possibility of the presence of tuberculosis was increased. (3) In a person without definite physical signs or symptoms a positive complement fixation test did not mean that tuberculosis was present. (4) With definite symptoms and signs a negative test did not exclude tuberculosis, though in such cases a Wassermann should be made. The man would make the best diagnosis who most carefully correlated the findings of the *x*-ray, the laboratory and the physical examination.

Dr. James Alexander Miller said that he shared the disappointment all felt in not having Major Stoll's presentation of the motion pictures. It would have afforded in a graphic way an opportunity of seeing some of the things done by those who had shared in the teaching under the Surgeon General's office of the American Army. He was particularly happy to discuss this phase of the subject because the first impression one got after studying the medical situation in the Army was one of intense admiration for the system developed in the divisions of tuberculosis. It was not taking credit from anyone to say that it was due to the remarkable organization of the service under Colonel Bushnell, who formulated and standardized the methods established for the Army, that they were enabled to establish a rational basis for the diagnosis of tuberculosis. Colonel Bushnell had standardized the methods of teaching throughout the various teaching centers in this country. This work had had and would continue to have a great effect on the medical profession throughout the United States. This method had also been carried out in France under Major Webb with the entire American forces in France. There were several points he would like to emphasize. The first was that they had been able in the medical service to demonstrate the possibility of making a very fair proportion of accurate diagnoses by rather rapid methods, simply by utilizing a system. He thought that before the war all would have been extremely skeptical in regard to this "rapid fire" method required by the exigencies of the situation in the Army. When it came to checking up the results obtained by men accustomed to spending one-half to three-quarters of an hour in making an examination with those reached by the same men using the systematic methods of Colonel Bushnell it was found that the errors were very slight, less than 10 per cent. This showed that perhaps tuberculosis specialists in their efforts to arrive at an early diagnosis of tuberculosis had overemphasized the need of fine points to reach accuracy. It also brought out that not on the signs in the chest alone did the diagnosis of tuberculosis rest, but that the *x*-ray, the symptomatology, and the laboratory findings must be taken into account. There had been for a number of years a tendency to overrefinement in diagnosis in their endeavor to find the active cases in need of treatment. They had followed this tendency with the idea of correcting slipshod methods, with the result that time was lost and there was perhaps a clouding of their ideas by the multiplicity of details which they were accustomed to give attention to in arriving at a conclusion. A second remarkable result of the systematic teaching of men not supposed to be experts, and this was a hopeful sign, was that it was shown that these men could arrive at very correct conclusions. Because of this systematic method, at the time of the draft and later in the base hospitals and cantonments only about 500 cases of tuberculosis had been sent back from the forces in France. Major Webb had told him that he found many men under suspicion but few that proved actually to be cases of tuberculosis. The difficulty was that they had many other infections, particularly streptococcus infections, which simulated tuberculosis and many other conditions which were subacute or even chronic, which simulated but were not tuberculosis, and these cases did not need the treatment that tuberculosis cases required. Another phase of tuberculosis work was opening up for which we would be indebted to the Army and that was in reference to the care of patients after their discharge from treatment. The Surgeon General's office would care for the tuberculous soldier before his discharge, and after his discharge, and later under the Federal Vocational Board he would be taught how to get back to life. In this part of the work the methods employed were somewhat similar to those in operation for the rehabilitation of the multilated. It had been the experience of those handling the tuberculosis problem that there were many relapses after the patient left the sanatorium, and this was due to the fact that insufficient attention had been paid to reinstating the discharged patient into an ordinary environment. The plan for the rehabilitation of the discharged tuberculous patient was divided into two parts (1) vocational guidance, that was, consultation with an expert who would assist the patient in selecting a suitable employment, and (2) education in the occupation chosen. This work had been begun in England and France where it had taken the form of industrial colonies. When the patient first entered an industrial colony he started with some form of recreational occupation, and as his condition improved the amount of work given him was increased. In France and England much of the instruction was along agricultural and horticultural lines, and various occupations that had to do with country life. In New York, however, the men did not seem to take so readily to country life. They were also taught various handicrafts and trades, and among these the manufacture of articles by the use of industrial machinery in open-air shops had been found a particularly suitable occupation for the tuberculous patient. In these shops they were taught to work in both wood and metal, and a man who acquired skill in one of these lines could easily adapt himself to work in the other, and he was thus put in a position where he could command good wages without undue overstrain. Under the direction of the Federal Vocational Board vocational reeducation was to be established in connection with the base hospitals and with the work for tuberculous patients fresh air work shops would be established. The first open-air shop for the vocational training of discharged tuberculous patients in civil life was being planned through the cooperation of the United Hebrew Charities and the Joint Tuberculosis Committee, and this was a distinct advance in the methods of handling the tuberculosis problem which had come from the war. Dr. Miller stated there were one or two very definite lessons that we had learned from the war which had a very great bearing on our attitude toward tuberculosis. The first of these was that a man with a quiescent tuberculosis could do a great deal more work or take a great deal more exercise than we had thought he could, provided he did it regularly. That fact had been demonstrated by the armies, for in the French Army there was less tuberculosis than among a similar group of men in civilian life; in the English Army there was less tuberculosis during the war than when the army was on a peace basis, and the same was true of our own army. Evidently army life developed less tuberculosis than we had feared. The second lesson was that the increase of tuberculosis during the war was not due primarily to overcrowding or industrial overwork, but was largely a question of food. It was noticed that wherever there was a shortage of food there one would find an increase in tuberculosis. This gave them a very definite cue in the prevention of tuberculosis, namely, that instead of trying so strenuously to keep people from becoming infected it would be better to spend more time in trying to build up the resistance of the individual and to see that he was well nourished, particularly the poor children, for in this way their susceptibility to tuberculosis would be diminished. This might have a very definite influence upon the whole antituberculosis campaign.

The Diagnosis of Tuberculosis from the Standpoint of the Radiographer.—Dr. Lewis Gregory Cole made

this presentation. He stated that it was his intention merely to discuss the paper of the evening, and that rather briefly, when he had been asked if he had any cinematographs, and, if so, whether he would exhibit them. He happened to have one which, though not on the subject of the evening, he had been asked to present. He wished first, however, to show a schematic diagram which he had used for his own aid in the study of tuberculosis. It was not entirely his own, but was devised by the cooperation of his associate, Dr. Steiner. This diagram consisted of a checker board, with five squares in the vertical direction and four in the horizontal. To the left of the squares in the vertical direction were the terms calcified, fibroid, miliary, pneumonic, cavity (the pathological arm). The four columns of squares from left to right were designated hylus, bronchi, pleura, parenchyma (the anatomical arm). He felt that the diagnosis of tuberculosis by the *x*-ray must be based on the *x*-ray recognition of pathological lesions, nothing more and nothing less, and there were just five types of pathology recognized, namely, calcifications, fibroses, miliary involvement, pneumonic involvement, and cavity formation. Each one of these types might involve the hylus, bronchi, pleura or parenchyma. Thus with this diagram one could readily check the nature of the involvement and the part affected. For instance, if one found a calcification of the hylus he placed a check in the first square at the upper left-hand corner of the checker board; if there was a calcification of the bronchi the check would be in the second horizontal square. They had found that by drawing a diagonal line from the lower left-hand corner of the checker board to the upper-right corner the cases falling in the squares through which the line passed might be classified as borderline cases; those falling in the squares above were not of significance as clinical tuberculosis, and those falling in the squares below those through which the diagonal line passed were clinical tuberculosis. Dr. Cole showed lantern slides of roentgenograms illustrating the various lung lesions and called attention to thickening around the bronchial and peribronchial structures which might be due to conditions other than tuberculosis, such as pneumonia, grippe, and various other infections. In borderline cases in which it was difficult to tell whether the tuberculous process was active it was their practice to have the patient come at the end of six weeks or six months for a second roentgenographic examination (and then by comparison of the radiograms one could tell whether the process was advancing or was quiescent. An interesting series of radiograms showed the progress of a case of pericarditis, with the gradual enlargement of the pericardial sac. Then after two tappings, at which 500 and 400 c.c. of fluid respectively were removed, the return to a normal condition was demonstrated.

Dr. Cole then exhibited a cinematographic reel showing the process of the peristaltic wave pylorusward, and the filling and emptying of the cap into the duodenum. The peristaltic action of the stomach in various pathological conditions, as ulcer in various locations, filling defects, and annular carcinoma were also shown. The reel had been produced by using film eight inches wide and making thirty exposures in twelve seconds.

Dr. Dudley D. Roberts spoke a few words of appreciation in regard to what the Army had done in teaching the diagnosis of tuberculosis to the medical practitioner. He said that before the war all medical men thought they knew something about the diagnosis of tuberculosis, though perhaps not as much as the specialists in that field, but he felt sure that his sentiments would be voiced by every man who had been in the service when he said that it was marvelous what had been accomplished in giving a better and clearer insight into what was and what was not tuberculosis. Even the specialists had learned something of what could be done by the x-ray in the diagnosis of tuberculosis, and had come to recognize that it was a great aid. Of course, a few mistakes in diagnosis were made, but they were decidedly more on the part of the clinician than on that of the roentgenologist. The epidemic of influenza had greatly increased the opportunities for mistakes in the diagnosis of tuberculosis, since among those having had influenza there were many cases of peribronchial involvement which were to a certain extent suspicious of tuberculosis. These patients frequently remained ill for a considerable length of time. The physical signs, however, were not highly suggestive of tuberculosis, but when it came to the *x*-ray findings one had to be on the alert or he would be led into much confusion.

Dr. Alfred Meyer said he had come to the meeting prepared to learn how a diagnosis of tuberculosis could be made by an appeal to the eye alone, and how such a method could compete for teaching purposes with the older methods. Men who made a specialty of the subject had been successful with methods that appealed to the eye, ear, and sense of touch in diagnosis, and he could not refrain from wondering how a method that appealed to the eye alone could compete with them. He felt strongly convinced that most men doing chest work would agree with his point of view. He felt that the eye played a small rôle as compared with that played by the ear and the sense of touch, for by the eye they could learn only what was shown in the pictures. He wondered whether men teaching the diagnosis of tuberculosis in the wholesale way by appealing to the eye alone could get results equal to those who instructed by taking a few men at a time into a small, quiet room and pointing out to the men individually the method of making the examination, including percussion, palpation and auscultation. He hoped that at some future time Dr. Stoll would give the demonstration they had missed to-night. He also wished to emphasize the fact that it was not quite fair to cast aspersions on the men who had gone into minutiæ in making physical examinations and who spent a half or three-quarters of an hour in one such examination, for often it was just one small link obtained in this way that completed the chain and enabled them to make the diagnosis. In taking this stand it was of course to be understood that he was not referring to the obvious cases of tuberculosis, but to those incipient cases that were not infrequently a subject of dispute between the *x*-ray man an the clinician, and between the War Department physicians and physicians in civil life.

Major Stoll, in closing, said that perhaps he had not made it quite clear that the pictures were employed as an aid in teaching the diagnosis of tuberculosis. They were teaching not only what the ear could hear, but *how to listen*, in what position to have the patient and what to tell the patient to do to bring out râles. It would be most unfortunate if the impression were carried forth that they deprecated a painstaking examination, or that they advocated slipshod methods, but by having a definite system and saving unnecessary motions, five or ten minutes could be saved in the time required for examination, which was certainly an advantage. He felt sure that if they saw a man examine a patient in a rather aimless way and then compared the procedure with a particular system which was applied with a considerable degree of accuracy they would appreciate the value of the latter. These pictures showed the incorrect methods of doing many things and the reason why they were incorrect, as for instance, in regard to illumination they demonstrated what was shown by direct illumination and what mistakes might be made if the illumination was slanting. They showed the difference in the physical signs when the muscles were tense and when relaxed, and what mistakes were made by a wrong pressure of the fingers. All the various features underlying palpation, percussion and auscultation were brought out by the pictures.

Nature of the Pandemic.—Chabas, writing from Valencia, insists that the second visitation of the pandemic in August-October was a malady differing entirely from the first visitation of May-June. He regards the second outbreak as brought from France by returning Spanish and Portuguese laborers. It is best to consider it a pneumonia pure and simple due to a hitherto unknown pneumococcus or filtrable virus. The question of dealing with future epidemics has been left to the distinguished bacteriologist, Ferran, who many years ago anticipated some of the most important discoveries in acquired immunity. With such a man in power it should result in a saving to Spain of 200,000 lives annually from the various epidemic diseases.—*Gazette des hôpitaux.*

APICAL TUBERCULOSIS AND THE ORTHOGRADE POSTURE;

AN HYPOTHESIS TO ACCOUNT FOR THE APEX OF THE LUNG AS THE LOCUS OF INCIPIENT PULMONARY TUBERCULOSIS.*

By W. F. R. PHILLIPS, M.D.,

CHARLESTON, S. C.

PROFESSOR OF ANATOMY, MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA.

HYPOTHESES and theories are tenable and to be judged only so far as the postulates on which they are founded are real and not merely apparent. Future observation and investigation may show that some of the accepted propositions of today relative to human tuberculosis are either misinterpreted or erroneous. The apparent conditions relevant to the subject of this paper may be summarized as follows:

Tuberculosis in infants is glandular and abdominal; in adults it is pulmonary and, almost always, apical in the beginning. Between these two periods of life it is transitional, that is, it passes with varying uniformity of manifestation from glandular to pulmonary and from abdominal to thoracic as the individual passes from the infant to the adult. Collateral, and more or less synchronous, with this passage the orthograde posture becomes more and more the habitual posture of the waking hours of life. The passage from the supine of the infant to the erect of the adult introduces changes in the hydrostatics and hydrodynamics of the circulation which the organism is obliged to meet. Under the influence of gravity the blood accumulates in the more dependent portions of the great vascular reservoirs of the body in greater or lesser degree, depending on the intrinsic tonicity of the vascular system and the extrinsic tonicity and activity of the somatic musculature. Any and every change of posture from supine to erect requires a readjustment of the blood distribution and, conversely, from the erect to the prone or the supine. For example: In the supine posture the capillaries of the dorsal portion of the lungs, from apex to base, will be flooded with blood, while the ventral capillaries will not be well filled and, indeed, may be all but collapsed; changing to the upright posture, the basal portions of the lungs become hyperemic and the apical portions anemic. Analogous changes take place in the liver and all other parts of the body. The dynamics of the circulatory apparatus are called on to vary their activities to meet these variations in the statics of the circulatory distribution of the blood. To give an illustration: The blood column in the venæ cavæ must always be at the level of the highest point of the tricuspid orifice; if it be not, the ventricle is not filled when systole takes place. In the supine posture gravity alone will maintain this level; in the erect posture gravity alone will displace this level to the vena cava inferior and to a point below the level of the diaphragm. Yet in the erect posture the blood column fills the inferior vena cava and upward to the highest point of the tricuspid orifice. To maintain this inferior level, or meniscus, of blood always at and no higher than the tricuspid valve is one of the functions of the postural tonus of the abdominal muscles and of the unstriped muscular tissue of the abdominal viscera; because the contractile power of the veins and capillaries is not equal of itself to accomplish the task. This postural tonus is the resultant of dynamic activities called into play in the tissues concerned; it is not a static or passive condition. All this has been established experimentally by numerous observers.

These changes in the static and dynamic conditions of the organism occasion many and complex changes and readjustments in the other functions of the body. To review them even synoptically is not practicable in a single paper. Even to present all the phases of these adjustments and readjustments that may play important parts in the hypothesis which is addressed to your attention is not practicable; only some two or three of the manners in which the changes of the blood distribution, due to postural changes occur, can be considered. The degree of physical and physiological efficiency with which the organism responds to these changes is one of the measures of the organism's preparation for living, of its fitness to survive.

The hypothesis formulated on the facts and postulates thus briefly referred to may be stated as follows: In the assumption of the orthograde posture gravity causes the bulk of the blood of the pulmonary circulation to flow through the lower portions of the lungs; the capillaries of these portions are filled to a certain degree of overdistention, while the capillaries of the upper portions, particularly the apices, are but meagerly filled with blood and their walls are more or less collapsed; the resultant being that conditions are produced which afford opportunity for the lodgment and development of the tubercle bacillus in one or more of the manners to be set forth. As a lemma to this hypothesis, if under the hydrostatic conditions imposed on the circulatory mechanism by the assumption of the upright posture the organism is able to

*Read before the American Climatological and Clinical Association, Atlantic City, N. J., June 18, 1919.

maintain a certain minimum circulation through the apices of the lungs, apical tuberculosis will not develop, and, as a corollary, pulmonary tuberculosis as a primary disease will not occur. However, this hypothesis should not be taken too rigorously, because we must admit that there is still question as to just where in the lung tuberculosis makes its beginning; whether it is essentially a lesion of the pulmonary parenchyma, or an extension by way of the lymphatics from the lympathic glands, or by the blood stream from these glands, or from some other primary locus elsewhere, and, finally, whether there is any locus of the lungs more peculiarly susceptible to tuberculosis than another.

At this point, it will be well to mention some of the theories and hypotheses previously advanced to account for the generally accepted view that the apex is the almost invariable locus of incipient pulmonary tuberculosis in adults.

Freund[1] advanced as an explanation the existence of symmetrical and asymmetrical stenosis of the upper thoracic aperture. Birch-Hirschfield suggested abnormalities of the bronchus apicis posterior. Pressure of the first rib on the apex was assigned by Schmorl, and exostosis of the angle of Ludwig by Rothschild. Campbell[2] suggested as a cause the intra- and extra-thoracic conditions of the apex of the lung in relation to the effect of atmospheric pressure. "The extreme apex in man," he writes, "being extrathoracic, . . . on inspiration the intrathoracic lung is under a pressure less than that of the atmosphere, but the apex is subject to the atmospheric pressure which is communicated to it by the soft parts covering it; this air meets the incoming air from the trachea and large bronchi, and the pressure becomes equalized. The result of this is that on inspiration only a small quantity of oxygenated air reaches the apex. Again, on expiration, the pressure on the apex being that of the atmosphere, and hence less than that of the rest of the lung, air rich in carbon dioxide, but poor in oxygen, is forced into it. From the above it follows that the contents of the apex are under most unfavorable conditions for becoming aerated, and the vitality of the tissues is lessened, and hence their resisting power is lowered." Jones[3], studying the anatomical relations of the apices in relation to phthisis, explains apical tuberculous infection as due to the close relation of the dorsal apical portions of the lungs to the thoracic and the right lymphatic ducts; these two vessels being separated from contact with the lungs in this region only by the thickness of the two pleural membranes. Jones discovered an actual case of incipient apical tuberculosis involving the thoracic duct at this locus. From the pathological appearances, Jones was inclined to regard the duct as the primary seat of the lesion in this case, hence his theory of the mode of infection. Aufrecht[4] has advanced the theory that the bacilli gain entrance to the great veins and find lodgment in the terminals of the pulmonary arteries at the apex. But how it comes about that these arteries afford such lodgment more than the other arteries is not stated. Bonney[5] accepts Aufrecht's theory, which he states "effectually disposes of the common error that the site of the initial lesion is indicative of the point of entrance of the bacillus." According to Bonney, Aufrecht's theory has been experimentally verified by Calmette, and others. The hypothesis I here offer is consonant to a certain degree with Aufrecht's theory, though it is not offered either as a support or a modification of that theory.

The total quantity of blood in the human body has been variously estimated, and different values obtained by different observers. What may be regarded as the probable mean is that the blood constitutes 7 per cent. of the body weight. According to Leonard Hill[6], from 50 per cent. to 70 per cent. of the total blood of the body is in the abdominal and thoracic viscera during inactivity, and about 36 per cent. in the muscles when at rest. When active or working about 66 per cent. of the blood is in the muscles. The abdominal and thoracic viscera, therefore, are in reciprocal relation with the muscles of the body during rest and exercise. The mechanism by which this reciprocal relationship is maintained is complex, and its consideration cannot be entered into here. It is, however, the physical and functional efficiency of this mechanism that determines the reaction of the blood and the lymph circulations to the static influence of gravity, and which regulates the volume of blood that at any moment may be found in any part of the circulatory system.

Experiments on animals have shown that not more than one-third of the pulmonary vascular system is required to convey the pulmonary blood under the ordinary conditions of rest and moderate activity. Clinical observations on man have shown, over and over again, that at least one-half of the lungs can be consolidated to a degree inconsistent with its functioning as a part of the pulmonary circulatory system, and yet the circulation go on without any observable impediment. These facts indicate that under normal conditions of rest and moderate activity not more than half the capillary system of the lungs is necessary to carrying on the circulation. However, it does not follow necessarily that there is no blood flowing through all the capillaries, but it does follow that the same rate of flow and a full volume of blood are not maintained in all the pulmonary capillaries at all times and under all conditions. There is not the muscular mechanism in the thoracic cavity for aiding the capillary vascular system of the lungs that there is in the abdomen for aiding that of the abdominal viscera. The only effective muscles of the thoracic cavity are the unstripped muscles of the blood vessels themselves, and very indirectly the diaphragm. Whilst the capillaries are devoid of muscular tissue, they have, however, a certain contractile power, resembling that of the ameba somewhat, by which they may vary their caliber, as seen in their reactions in the phenomenon of inflammation; but this power is of short endurance and is soon exhausted for the time being. It is not probable, in the present state of our knowledge, that these capillaries can so alter their calibers as to maintain for any length of time against the influence of gravity a uniform distribution of blood throughout the pulmonary mass; what we know is against such a possibility.

The great vascularity of the lungs is such that each lung may be regarded as a single blood vessel of its own shape and size, and, as such, subjected to the hydrostatic pressure of its contained volume of blood, with this important exception, that instead

of rigid walls, or even of the strong musculo-elastic walls of the systemic arteries, the walls of this lung vessel are easily distensible and do actually distend considerably under the hydrostatic pressure of its contained fluid. The extreme vertical height of the lungs is approximately 7 inches. The hydrostatic pressure, if the lungs were filled with blood, would vary from zero at the apex to 13 mm. Hg., in round numbers, at the extreme base. The pulmonary vessels enter and emerge from the lungs a little above the midpoint of the vertical pulmonary plane. The capillaries below the level of the pulmonary veins, be the position of the body what it may, are of necessity always full of blood and distended to a degree dependent on their intrinsic resistance and the hydrostatic pressure prevailing at the moment; those above the level of the veins will contain varying volumes of blood and be under varying hydrostatic pressure, according to the volume and the rate of flow of the blood through the pulmonary system at the time, and these will depend on the physiological activity and demands of the individual at the time. In the erect posture the basal capillaries will be subjected to a hydrostatic pressure of from greater than zero at the level of the lowest pulmonary vein to 6 mm. Hg., in round numbers, at the lowest level of the lung. Any increase in pressure due to the existence of a higher blood column level in the lungs will be additive to these pressures.

As already stated, experiments and clinical experience have demonstrated that the vascular system of the lungs is more than double the capacity needed to convey the volume of blood continuously flowing through them, therefore it follows that there are many times when considerable spaces of lung capillaries above the pulmonary vein levels are virtually devoid of blood. The walls of these capillaries will be more or less collapsed, introducing a greater resistance to the passage of whatever blood stream there may be moving through them at the moment. If foreign particles, such as germs, carbon, silicious, and other sorts, should be in the stream, they will be more than likely arrested in these narrowed or collapsed capillaries. It is conceivable that in this way tubercle bacilli if in the blood stream, as postulated by Aufrecht in his theory of tuberculous infection previously referred to, may be filtered out, that is, jammed between the endothelial cells of the capillaries, cells endowed with phagocytic properties, which engulf these and other foreign matters brought in intimate and sufficiently prolonged contact with them. Under certain conditions, such as fatigue, heredity, and the other things of the somewhat long catalogue of predisposing causes that we take refuge in, it is conveivable that the phagocytic proclivity of these endothelial cells when associated with a diminished, or even absent, phagocytic power may be the actual way in which the bacillus is planted in the interstitial spaces in which it subsequently grows and multiplies. Aufrecht[6] states that in incipient cases of porcine tuberculosis he has found the bacilli actually in the walls of the blood vessel. But this is not the sole way by which this relation of the vascular capacity of the lungs to the blood volume and the physiological consequences of this relation incident to postural change, may be connected as etiological factors in the predilection of incipient tuberculosis for the apical regions. A large speculative field is opened which it is not possible to explore in the time at present available. I shall refer but briefly to two or three other possibilities.

It is conceivable that the relative absence of a blood stream for considerable periods, two, four, six, eight, or more hours, as must often obtain in the apices when the body is erect, may of itself induce changes in the endothelial, or the epithelial, or the interstitial cells, or all three, that may make them more susceptible to the invasion of tubercle bacilli. It is conceivable that there may be quite a deleterious effect on both the endothelial cells of the capillaries and the epithelial cells of the air sacs caused by an excess of oxygen in the apical alveolar cells. Or, to put it another way: In the absence of an adequate blood stream passing through the apical capillaries, the oxygen actively taken up by the respiratory epithelium not being taken away rapidly enough becomes in itself more or less noxious to these very cells; or the deficient blood stream may interfere with the carbon dioxide balance of the apical tissues, and these tissues may become too poor in carbon dioxide, as well as too rich. Deficient oxygenation of the red cells of the blood has so long held the center of the stage that we lose sight of the fact that an excess of oxygen is harmful to tissues, quite as much so as a deficiency. The elimination of carbon dioxide has also been so emphasized that we forget that the retention of a certain amount is quite as vital to life as the absorption of oxygen; that the balance between these gases cannot be disturbed for long either way without seriously jeopardizing the health of the organism.

One other speculative condition will be mentioned. The pulmonary arteries going to the upper lobes approximate at the points of their branching off the continuation of the tangents of the curves of the two main divisions of the pulmonary artery, and are, therefore, more likely to be the pathways of any of the lighter particles in the blood stream. It may be that in the long run, owing to their less specific gravity, more leucocytes, relatively, pass through the upper lobes than through the lower lobes. Because of their wandering habits many of these leucocytes have engulfed perhaps tubercle bacilli, and those that pass into the upper lobes are likely to be slowed down or arrested in the more or less collapsed capillaries of the apical regions from which they again wander, going into the interstitial spaces and air sacs, carrying in and depositing their contents, bacilli, carbon, etc., taken up by them elsewhere in their previous wanderings. As an observed fact, the upper lobes, and the upper part of the upper lobes, show usually the earliest and densest pigmentation. Bacteria free in the blood stream would be subject to the same reasoning.

If the assumption of the upright posture be really an etiological factor in apical tuberculosis, it should be expected that animals habitually pronograde, and such as are subpect to tuberculosis, should show analogous loci of infection; and this is found to be the case.

In 1894 Theobald Smith[7], in studying tuberculosis in cattle, found in 19 autopsies of dairy cows slaughtered because giving positive reactions to tuber-

culin, that the earliest evidence of the pulmonary disease was manifested quite regularly in the caudal lobes, and "in that portion of the lung tissue above or dorsad to the main bronchus, *i.e.* in that portion of the lung tissue which rests under the ribs at their vertebral attachment." This region corresponds physically with the apex of the human lung, that is, it is the highest part of the lung in the standing position of the animal. It is also the highest part of the lung when the animal is lying down, differing in this respect from the apex of the human lung. However, the caudal lobes were not exclusively the ones affected. Smith tabulated his findings as follows:

The large caudal lobes were affected in....	16
They were affected exclusively in.....	11
Both caudal lobes were affected in.....	6
Left caudal lobe alone in.....	5
Right caudal lobe alone in.....	5
Right cephalic lobe affected in.....	6
Right cephalic lobe affected exclusively in..	3
Left ventral lobe (with other lobes) in....	1
Right ventral lobe (with other lobes) in....	1
Left cephalic lobe (with other lobes) in....	1

It is particularly significant in this tabulation to notice that the ventral lobes were affected but twice, and not exclusively but in association with other lobes. Now the ventral lobes are the lowest parts of the bovine lungs, and in this respect are physically analogous to the basal lobes of the human being. Another interesting and relevant contrast indirectly brought out by the foregoing tabulation is that of the functional movements of the lungs in orthograde and in pronograde animals: The apex, the most frequent locus of incipient pulmonary tuberculosis in human beings, is the least mobile portion of the human lung; the caudal lobe, the most frequent seat of incipient pulmonary tuberculosis in the susceptible pronograde animal, is the most mobile portion of the pronograde animal's lung. The frequency of the caudal lobe as the seat of incipient pulmonary tuberculosis in animals has been observed by so many observers that we must accept the fact as established as firmly as that of the apex of the human lung.

It is relevant and significant to note, also, that Campbell[2], in 1891, as a result of his postmortems on animals of the Zoological Gardens, London, was struck with the similarity of tuberculosis in monkeys to that of young children. Campbell was particular in stating that the age of the monkey had no apparent effect on the tuberculous manifestation; it was the same in both old and young animals. He also stated that he "was struck by the fact that the apices" of monkeys' lungs, "instead of being more liable to the disease than other parts of the lung, are as a rule less affected." I think it will be admitted that the postural habits of monkeys and young children are not very far apart. This similarity of tuberculous manifestation in the young child and in the monkey lends, at least, additional color to the influence of posture as set forth herein. Certain of the current and approved therapeutic practices seem also to give plausibility to this hypothesis, and at the same time to receive from it a certain degree of physiological assurance of their own wisdom.

Recumbent rest is admittedly beneficial in the early and active stages of pulmonary tuberculosis, and exercise, in those stages in which the disease processes are nearing cure or passing into a condition of chronicity. In recumbent rest the diseased apical regions are absolutely more hyperemic, a large part of the blood from the previously overfilled and larger lower lobes being returned to them by hydrostatic pressure; and whatever defensive and offensive properties may be present in the blood, either naturally inherent or physiologically acquired, are brought into action at the seat of the disease. As long as recumbency is maintained the therapeutic effects of these properties are at a maximum, and if equal or superior to the power of the invading germs, stay or cure the disease, as the case may be. In exercise the demand for more blood in the muscles leads to its expulsion from the great vascular reservoirs of the abdomen, the liver, the spleen, and the intestinal vessels and capillaries. This additional volume of blood must pass through the pulmonary circulation, and it must continue to pass through as long as the exercise is kept up. As a result, the vascular spaces of the lungs are better filled and the diseased areas more or less flooded by this increased quantity of blood in the lungs.

In conclusion, it is right to state that I have found in the literature a number of allusions to the difference of the circulation in the apical regions as compared with the lower regions of the lungs, and as incidental to the assumption of the upright posture, also to the upright posture, as being a factor in the etiology of apical tuberculosis. But so far I have not come across any statement connecting the upright posture in just the manner I have herein suggested. However, the literature is so extensive that I have to plead the want of time to examine more of it than I have.

THE MALONEY METHOD IN THE TREATMENT OF ATAXIA.

BY MORRIS GROSSMAN, M.D.

NEW YORK.

INSTRUCTOR IN NEUROLOGY, COLUMBIA UNIVERSITY; ADJUTANT VISITING NEUROLOGIST, MONTEFIORE HOME AND HOSPITAL; ADJUTANT VISITING NEUROLOGIST, CENTRAL NEUROLOGICAL HOSPITAL; ASSISTANT NEUROLOGIST, MOUNT SINAI HOSPITAL DISPENSARY AND VANDERBILT CLINIC.

THE method of treating tabetic ataxia that Maloney has elaborated is based upon the thesis that perfect thinking is essential to perfect moving; and that perfect moving is the outward sign of perfect thinking. Training in perfect thinking is, therefore, training in perfect moving; and training in perfect moving is training in perfect thinking.

Maloney emphasized the fact that there is a psychological as well as a physiological element in all symptoms, in all disabilities. This is especially true of the symptoms and manifestations of locomotor ataxia. Psychological treatment is, therefore, as essential as physiological treatment. Upon the reciprocal relations of the mental state and the tabetic symptoms, and upon the interdependence of these symptoms, rests the basis of psychological treatment. Without knowledge of these relations, effective treatment is impossible.

The deterioration of attitude in tabes, Maloney has shown to be due in part to anatomical, but mainly to mental causes; and as such it is readily influenced by proper therapy. As an aid to the rapid correction of faulty attitude, and to prevent as much as possible its aggravation, Maloney has introduced into his method of treatment the temporary use of mechanical measures in the form of plates for the correction of defective arches, shoes, and braces to counteract weak and hypotonic muscles.

The mental state, fatigue, and fear, Maloney combats with "rest exercises"; and lastly he has introduced blindfolding into his method as a measure to decrease external distraction, thereby allowing greater concentration and more intensive application for interpreting the delayed, imperfect, postural images that result from interference in conduction of sensory stimulæ.

Of the 15 cases reported here, 10 received antispecific treatment either at the time when they had their chancre, or at a later date when involvement of the cerebrospinal axis was probably evident. Some of these patients had received what might be considered adequate treatment, or nearly adequate, both at the time of their primary infection and at a more recent date; yet the disease, with the exception of slight evanescent improvement in some of the symptoms, relentlessly progressed. In others there was no improvement, and in some aggravation of the symptoms was definite. While receiving this mental treatment, with the exception of 2 cases, no salvarsan or mercury was given.

The length of time devoted to each patient was governed by his mental and physical capacity for work, the average being about one hour 4 or 5 times a week. The average length of time required to cure the ataxia in this group of cases was 8 to 12 weeks. This period can be considerably shortened by intensive treatment.

I shall first describe the mental state usually found to a greater or less degree in all ataxic tabetics, and the treatment of this state; and follow this with a description of the treatment of the motor symptoms, in a moderately severe case of tabetic ataxia.

The Mental State of the Tabetic.—Life with tabes is exhausting. To endure pain, crises, and other manifestations of tabes taxes the strongest; to work in pain, fear, and depression requires great effort. The effort demanded by day soon exceeds the recuperation obtained in painful sleepless nights. Slighter and slighter efforts, either physical or mental, fatigue the tabetic and quicken his pulse and respiration. The many perils to which an ataxic tabetic is daily exposed become increasingly harassing. Fear complexes readily form, and as they become elaborated and succeed one another, they tend to produce an unrelieved state of mental perturbation. Thus the tabetic may show dread of the dark, of the open, of changes of level, of traffic and street crossings, etc.

As the tabetic is attacked by one after the other of the unexpected and mysterious symptoms of tabes, he loses heart. He feels increasingly his lack of competence to cope with his business, social, and domestic affairs, and he becomes more and more depressed. The tabetic, depressed, irritable, fearful, weary, sleepless, and emaciated, becomes less and less competent. Unenlightened treatment fails to relieve or check his symptoms; the disease obviously advances.

The mental stress of living with tabes varies from time to time according to the changes in circumstances; favorable with rest and reassurance and in remissions of pain and crises, unfavorable in fatigue and suffering. Maloney has shown that during the course of the disease, the average daily mental state tends gradually to deteriorate. The rate of this deterioration is determined by the cerebral power of the patient, by the rapidity of development of the anatomical lesions, and by the conditions under which the tabetic lives.

The effect of the various symptoms upon the mental state varies with their nature and intensity; paresthesias may be less pernicious than pain or crises; ataxia more demoralizing than blindness, etc. Just as the symptoms react on the mental state, so the mental state reacts on the symptoms. In favorable mental states, pain, ataxia, crises, and other symptoms of tabes are diminished; in unfavorable mental states usually increased. The attitude of the ataxic tabetic is largely an expression of the fear and tension under which he lives; this attitude is muscular, with cardiovascular and respiratory accompaniments.

For the treatment of this constrained attitude, Maloney devised the following "Rest Exercises". A quiet room preferably darkened, with a bed or couch wide enough to keep the patient's arms from hanging over the sides, when relaxed; a small cushion for his head, and a metronome to regulate the time are the only appliances required. The patient in a recumbent posture, with the clothes about the chest and abdomen loosened, is instructed to breathe deeply and to pause at the end of inspiration and expiration. After a few deep respirations the patient passes to breathing of moderate amplitude, and later to gentle breathing. The breathing is abdominal in type, slow in rate and uniform in rhythm. Distracting thoughts are stopped as they arise, and his attention must be kept fixed on the sensations that accompany his breathing. A bag of shot or sand placed on the abdomen, increases the muscular effort so that the breathing may not readily lapse into an unconscious act.

Then muscular relaxation is procured. To induce this state, the muscles are passively moved at each joint. The muscles of the scalp, forehead, eyelids, and jaw are passively moved until wrinkling, and blinking of the eyelids diminish and disappear and muscular spasm has been reduced or eliminated. Next a shoulder is relaxed, then an arm, each in turn must be passively moved until muscular spasm vanishes and the part lies motion-

less and flaccid, and falls limply from any unsupported position. After a part is relaxed those previously and that newly relaxed should be briefly dealt with again in the order in which they were first relaxed; this linking of parts previously relaxed to parts newly relaxed is helpful in bringing the whole to a satisfactory state of relaxation. The relaxation of the neck and trunk muscles is best accomplished while the patient sits. The patient's arms should then hang limply by his side, and his feet, crossed one over the other, should rest on their outer borders. The head should next be passively rotated in all directions, slowly and repeatedly; then by moving the supported trunk, the head is allowed to fall passively backward and forward, by its own weight. Finally the head rests with the chin upon the chest, or hangs forward suspended by the ligaments of the neck.

The trunk should be slowly bent backward and forward and from side to side, until the muscles are relaxed and allow the trunk to gravitate without restraint in whatever direction it is inclined, unsupported.

Throughout the passive movements, the physician periodically corrects the breathing, slows it as it quickens, insures adequate pauses at the end of inspiration and expiration, and encourages rhythmic movements. The objective guide to success is the behavior of the eyelids. When the patient is well relaxed, the eyelids are still, the pulse rate has slowed, and the blood pressure has fallen; when quivering of the eyelids returns, the patient is uncomfortable or distracted; the pulse rate is increased and the blood pressure has risen. The training usually begins with several 10-minutes exercises, separated by short intervals. As the patient learns, the exercises may be increased to 45-minute periods. The easier the patient learns the less is the strain upon him, and the more pronounced is the relief of his muscular, vascular, and mental tension. The tabetic thus trained to rest is endowed with the necessary preliminary to all effort—the power to recuperate.

Treatment may now be directed toward training his cerebral control. Movements of the head, eyes, and other simple muscular exercises are of great value; in addition to these, the "Reckoning Tests," as described by Maloney (*Rev. of Neurol. and Psychiat.*, July, 1911), can be used with great benefit. All movements must be accurately defined, and precisely performed; they must be carefully regulated in their time relations by means of the metronome. Eye movements may be done at first singly then conjointly; they should be of prescribed direction, extent, and rate. The training in the rest exercises is itself the beginning of the training in attention and in sustained and controlled effort.

The more an ataxic walks uncorrected, the more ataxic he tends to become. It is difficult to cure a symptom which is constantly being aggravated. The following mechanical measures were suggested and devised by Maloney for the immediate reduction of ataxia. These measures are used only as temporary aids, and are discarded as soon as the ataxic regains control of his movements; and the muscles are sufficiently developed to carry on their normal functions.

When standing or walking the average ataxic tabetic rotates his feet outward and in a horizontal plane, around a vertical axis, which passes through the ankle joint, to such an extent that the distance between the great toes may be several times that which separates the heels. These abducted feet

Fig. 1.—Foot-prints. 1 shows the imprint of the foot without the body weight; 2 shows a marked spread, due to hypotonia, when the body weight is carried.

are usually overpronated and in some cases, on account of the hypotonia and constant stretching of the ligaments, the anteroposterior and the transverse arches yield. Such a foot affords poor and inadequate support; the only stable element in it may be the os calcis.

The lack of support that such deformed feet afford to the swaying tabetic creates in him not merely uncertainty in every step, but even a lively fear. The instability and fear result in excessive expenditure of muscular and nervous energy and contribute largely to fatigue. For the correction of this condition Maloney has devised a plate for the arches. This plate is constructed from models of casts of the foot taken when at rest and when the foot is bearing the body weight. The plate is a modification of the Whitman plate. The inner lip is curved below the level of the scaphoid; the outer flange is lower and does not extend so far forward; the support of the transverse arch extends out-

Fig. 2.—Showing various degrees of arch deformity.

ward beneath the inner four toes. When the spread is very great, the inner lip is extended forward to include and completely surround, on the inner side, the first metatarsophalangeal joint. The plate is further reinforced by using a high shoe. The last

of this shoe is straight and an extension of the sole three-eighths of an inch wide is recommended. A hickory-wood filler extends from the heel, through the shank, to the front of the sole, rendering the sole rigid and unbending. The heel is wedge-

Fig. 3.—Showing marked hypotonia at the knee-joint, resulting in genu recurratum.

shaped with the base of the wedge on the ground; it is seven-eighths of an inch high, and is partly cork to insure lightness. The box of the shoe is high; the tongue is thick and soft so that the shoe can be laced tightly; the ankle is reinforced with a small leather brace inserted between the lining and the upper. The special features of the shoe are its rigidity, its lightness, the increased ground area of the broadened heel and sole, and lastly the support around the ankle which prevents the ankle from yielding.

In addition to supporting the feet it may be necessary to buttress the knees and the back until the muscles are sufficiently strong to perform their functions properly. Overstretched muscles can neither reinforce joints nor recover their normal tone. Maloney prevents abnormal mobility of the joints by the use of braces; the braces are made of canvas or nonelastic webbing, and are attached to a belt around the waist. The mode of application depends upon the case. For cases in which abduction and outward rotation of the lower limbs is present, the bandage or strip of webbing is fastened to the loop at the back of the shoe; it is then carried to the outer side of the leg and wound spirally around and up the leg; two spiral turns, one of which passes behind the knee, usually suffice. The free end is passed around the waist and fixed to the belt on the opposite side. (See Fig. 4, A.) The shoulders may be braced by a double spica or cross bandage as at B in Fig. 4. The bracing helps to correct the faulty attitude which is perpetuating the fear and fatigue of the mental state. It stabilizes the ataxic and enables him to carry on activities with a minimum effort. The braces must be gradually loosened, and one by one discarded, as the muscles regain their tone and equilibrium and coordinate movements are again established.

After analyzing and measuring the disturbance of movement present in a given case, and after adopting such measures as are indicated to prevent the further aggravation of the disordered movement, one can begin to cure it. Impulses from the muscular apparatus and from the labyrinthine organ are constantly exciting in the cerebral cortex kaleidoscopic postural images of the whole body, always changing, yet always related. Of the majority of these images we are unconscious. We are usually conscious, not of the postures of the various parts of the body, but only of their combined effect, of our relation to our environment. On account of imperfect, delayed, and feeble images and afterimages, that may be the only ones available where the sensory pathways have been interfered with, most tabetics, misled by these, eventually suppress them altogether and learn to guide and correct their faulty movements by means of their vision. They become visual automatons and unless they carefully scrutinize their movements they cannot move. To obviate this, Maloney introduced into his method of mental training, blindfolding. Blindfolding assures attention to these imperfect, delayed, and feeble images, as they are the only ones available, when coordinate movement is being taught. Blindfolding also decreases competition for attention between postural images and images derived from other sensory fields; it also reduces to a minimum external distraction.

The "Rest Exercises," previously described, help to reduce internal distraction, and obviate the unconscious muscular spasms and contractions that are so commonly present in these patients; and control the resulting fatigue. Both mentally and physically, the tranquil, blindfolded ataxic is in the most favorable state for training in normal movements. Throughout the exercises these optimal conditions must be maintained. The amount of effort demanded

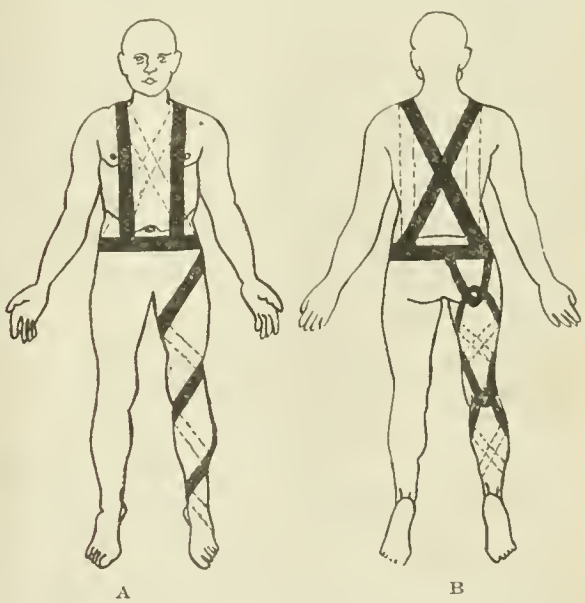

Fig. 4.—Showing bandages used as temporary muscles. A, bandage used to correct internal rotation; for external rotation the bandage is to be carried to the outer side of the foot. B, bracing of a tabetic whose back is weak.

from the ataxic must be carefully graded, and be well within his capacity for work. Rest and recuperation should follow. The initial exercises must be simple and well within the fatigue threshold. This initial training in cerebral control is best gained by the use of respiratory movements, eye movements, and movements of nonataxic limbs.

No successful movement is possible unless the relation of the body to its environment is stable; movements should be grafted only upon well balanced attitudes. The recumbent, the posture in which the equilibrium of the body is passively and mechanically assured, is occasionally the only posture which the ataxic can at first maintain; but almost invariably sitting is possible.

In the sitting posture he can gain valuable training in stability for the erect attitude. He may at first need an armchair to support the head and trunk; later he can sit erect on a stool without back or arms. Next, he practises with one, then with both arms outstretched at the level of his shoulders or held above his head. Finally in his outstretched arms he supports weights. Similar exercises are later practised in the kneeling and upright positions.

After the sitting posture, all fours (on the hands and knees) is learnt. When on all fours, the head should be held well up, the body should be straight with the thighs at right angles and parallel to each other; the feet should be slightly dorsiflexed and the toes should rest on the ground. If aid is required to maintain this attitude it should be freely given until it can be dispensed with. After stability on all fours is acquired, balance on the knees is practised. Care should be used to procure a proper upright attitude, with the head and trunk erect. After acquiring first sitting, next all fours, then kneeling, standing should finally be taught. The length of time for which a posture is maintained may be only a few seconds at first, but with repetition and practice this time is gradually lengthened; but it should always be kept well within the fatigue limit. Every posture should be learned blindfolded and should be practised until it becomes effortless.

With these postural exercises, movements should be taught. As no movement is permissible except in a correct, well balanced posture, and as the recumbent may be the only perfect posture, the movement exercises must often be first practised recumbent. The simple movements are the easiest ones to perfect and these should be the first ones taught. The perfection of a simple movement depends upon the perfection of its cardinal qualities, strength, direction, extent, and rhythm.

The beginning and the end of a movement should be definitely fixed. For direction and extent of movement, the physician passively performs the movement on the blindfolded patient. Then the patient resists this passive movement. Next the patient attempts to do the movement under the guidance of the physician; guidance is gradually diminished as the movement becomes more accurate. Finally the movement is done against the resistance of the physician. These resistance movements are of value for training in strength. The patient's head, trunk, thigh, or foot is placed in an attitude and the patient is asked to maintain this attitude for a given period of time, against the physician's effort to move it. The periods at first should be short, but gradually they can be lengthened; they should be timed audibly. These exercises may be varied by having the patient attempt to move against the physician's immobilizing resistance.

When teaching movements, we begin with general relaxation. After practising general relaxation, the patient's attention is focussed on the head; the shoulders are supported on a sandbag, and the head is extended; the patient is instructed to count slowly while the physician at a uniform rate repeatedly moves the head to a position of flexion, pauses, and then returns the head to the original extended position. Next the patient lightly but steadily resists the passive movement. Then the movement is practised with the patient performing and the physician aiding and guiding. The aid is gradually lessened as improvement occurs and the patient is able to do the movement alone. Finally the movement is done against the resistance of the physician. For rhythm and rate, a metronome may be used. A movement to be considered perfect must be well performed, at all speeds, and against resistance. The trunk is similarly exercised. After the head and trunk, movements of the limbs may be practised in the recumbent posture.

Again general relaxation and attention to the limb where movements are to be done. The postural sense loss, in the lower extremity, is less in the hip than in the knee, less in the knee than in the ankle, and less in the ankle than in the toes. The greater the number of surviving postural impressions in a joint the greater is the ease with which the movements at that joint can be made coordinate. Training in movements, therefore, should be started at the hip joint, then at the knee, and finally at the ankle. At first, only the simplest movement should be attempted—flexion and extension; later abduction and adduction. The knee exercises are practised by allowing the leg to hang over the edge of the couch for extension and the patient lying on his abdomen for flexion exercises.

In every instance, first relaxation, next passive movement, followed by passive resisted movement, then active guided. later active unguided, and finally active resisted movements, are practised. When these simple movements have been acquired at all of the joints, more complex ones, involving movements at two or more of the joints simultaneously may be taught. The movements learned in the recumbent position should be practised in the sitting, all fours, kneeling, and in the standing positions as these attitudes are stabilized.

When in the recumbent position the patient is able to perform all movements perfectly, and the "all fours" has been stabilized, progression on the hands and knees may be begun. When creeping, the knees should be well padded to prevent injury. Creeping is first performed, moving limb by limb at command. Thus at "one" the right hand is moved forward a slight distance; at "two" the right knee is moved forward; at "three" the left hand is moved forward; at "four" the left knee is pushed forward. Both the hands and the knees must move forward an equal distance, and in a straight line. To insure direction Maloney uses strips of linoleum; the width of these strips is diminished as the movement improves.

When proficiency in creeping has been gained, kneeling is practised. Next the body is balanced first on one knee, then on the other. Then one knee is slightly raised for a moment or longer if possible, and the body weight is balanced on the other knee. Progression forward on the knees, and side to side

movements are next learned. Finally walking is taught.

The blindfolded patient, standing, facing and near to a wall, shifts his weight from one foot to the other at command, for a measured length of time. This he practises until he can change his balance from foot to foot as fast as the metronome can beat. Next he practises raising himself on the toes of one foot, then the other, and then on the toes of both feet simultaneously. Next, without changing his place, he slowly raises one foot from the ground, then the other; gradually he increases the speed. Next, one foot is advanced and the body weight is thrown forward and backward from the rear foot to the advanced one; then the rear foot is brought alongside of the advanced one and progression is started. At command he advances either the right or the left foot. Then he begins to take successive steps at increasingly rapid beats of the metronome. He walks forward, backward, and from side to side. Finally, turning and walking up and down stairs are taught.

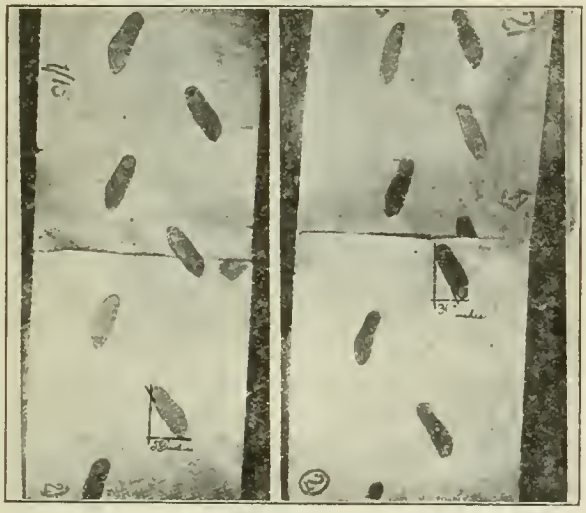

FIG. 5.—Case III, footprints of the patient. (See Figs. 6 and 7.) On the left are the imprints taken before treatment was begun; the picture shows the marked eversion of the left foot and the broad base used by the patient in walking. The picture on the right shows the correction in eversion and the narrower base after fifty treatments.

To avoid fatigue the exercises must involve a minimum effort. Relaxation must be freely practised during the periods of work; these periods should rarely exceed one hour. When the tabetic is mentally and physically competent to move coordinately in spite of all ordinary emergencies, under sheltered conditions, his activities should be broadened. He should be taught to walk freely and unaided in public, at street crossings, and at changes of level and surface.

With this method of treating ataxia, I was able to return to a nonataxic state, 12 of the 15 cases here reported. Most of these patients are still in a nonataxic state or were so when last seen or heard from. Nearly all were able to go about in public without aid; a few could not be induced to give up their stick when in public but they could get along without any aid from it.

It has been a remarkable feature in all of these patients, that their attacks of pain and their crises, have been much reduced in frequency and severity during and since the treatment has been given. The possibilities that this method of treatment offers to the unfortunate victim of tabes for relief of his most distressing symptoms, namely ataxia, pain, and crises, are indeed gratifying.

CASE I.—R M., 56, single, merchant. Referred by Dr. I. Abrahamson, December, 1915. Chancre 38 years ago; no treatment. Onset of tabes about 10 years ago with shooting pains, disturbance of vision; ataxia, and later diplopia, loss of bladder control, and loss of sexual power.

Physical examination: Right pupil larger than the left, both irregular and fixed to light reflex, with sluggish reaction to accommodation. Bilateral primary optic nerve atrophy. Absent ankle and knee jerks. Well-defined Romberg, hypotonia, and ataxia. After a course of treatment of about three months' duration the patient was discharged cured of his ataxia. About three months later he suffered a cerebral lesion that resulted in a hemiplegia on the right side, with motor aphasia. His reflexes remained unchanged. After a protracted illness extending over a period of 18 months, during which time the patient was bedridden and incontinent, mental training was again started. The patient regained control of his bladder and can now walk one mile or more without aid. There is still a slight inclination of the trunk to the left as a remnant of his hemiplegia.

CASE II.—F. B., 58; married; salesman. Referred by Dr. J. Braun. September, 1915. Chancre 20 years ago. Received mercury and iodides for two years following his infection. Recent treatment, 15 intravenous injections of salvarsan, and 7 intraspinally, and 30 intramuscular injections of mercury. Onset of tabes about 6 years ago, with disturbance of gait, shooting pains, and numbness of the extremities; later suffered from bladder, gastric, and rectal crises, with loss of sexual power.

Physical examination: Bilateral Argyll-Robertson pupils; ptosis of the left lid; absent knee and ankle jerks; well defined Romberg, hypotonia, and ataxia. Wassermann in blood 4 plus. After 10 weeks of mental training he was discharged cured of his ataxia. I heard from this patient in May, 1919, and he is still free from his ataxia and working as a salesman.

CASE III.—A. L., 43; married; butcher. Referred by Dr. J. Grossman. August, 1914. Chancre denied. Onset of tabes 9 years ago, with disturbance of gait, numbness and shooting pains in the legs. Ataxia progressively became worse so that 8 years ago he had to adopt a stick to enable him to walk in public. Has suffered from gastric crises, bladder disturbance and loss of sexual power. Blood Wassermann positive.

Physical examination: Bilateral Argyll-Robertson pupils; ptosis of the right lid; ankle and knee jerks lost; marked Romberg, hypotonia, and ataxia. Treatment for three months completely removed the ataxia and he was able to walk one mile in public without his stick when discharged.

CASE IV.—J. M., single; waiter. Treated October, 1914. Chancre denied. Onset of tabes 2 years ago, with shooting pains, numbness in legs, and ataxia; bladder disturbance and loss of sexual power. Blood Wassermann 4 plus.

Physical examination: Bilateral Argyll-Robertson pupils; ankle and knee jerks absent; marked Romberg and ataxia. I demonstrated this patient before the treatment was started before the Bronx County Medical Society, and then showed him after 6 weeks of treatment cured of his ataxia.

CASE V.—A. H., single; 31; merchant. Referred by Dr. I. Abrahamson, June, 1916. Chancre 14 years ago. No treatment at that time. In 1910 he received 25 injections of mercury intramuscularly. In 1912 he received 12 intravenous injections of salvarsan; from 1913 to 1915 he received 7 intraspinal injections of salvarsanized serum. Spinal fluid Wassermann 4 plus. Onset of tabes 7 years ago diplopia, shooting pains and ataxia; had to adopt a stick to get around in public. Later developed bladder disturbance, loss of sexual power, and desire.

Physical examination: Bilateral Argyll-Robertson

pupils; weakness of the right external rectus muscle; knee and ankle jerks absent; marked Romberg, hypotonia and ataxia. About 3 months of treatment was given and he left for his home cured of his ataxia. He felt so well and was improved so much that he

Fig. 6.—Case III; shows the patient standing without the aid of his stick; it well shows the broad base that he uses when standing or walking, the marked eversion of the left foot and the external rotation of his left thigh. The extreme alertness in watching where his limbs are, and what to do next with them; this anxiety and constant watching of limb movements is usually evident in most ataxic tabetics.

married, against my advice. I heard from him recently, and he is still free from ataxia.

Case VI.—H. K., 39; married; waiter. Referred by Dr. S. F. Weitzner, September, 1914. Chancre 19 years ago; no treatment at that time. In 1913 he received 3 intravenous and 1 intraspinous injection of salvarsan. From then to 1914 he received about 30 intramuscular injections of mercury. Blood Wassermann 4 plus. Onset of tabes 2 years ago with numbness, shooting pains in the legs, and ataxia.

Physical examination: Bilateral Argyll-Robertson pupils; absent knee and ankle jerks; well-defined Romberg, hypotonia and ataxia. After 8 weeks of treatment he resumed his occupation as waiter, free from ataxia.

Case VII.—L. B., 39; married; musician. Referred by Dr. F. Ob de Beck, October, 1915. Chancre denied. One year ago he received 9 intravenous injections of salvarsan and 12 intramuscular injections of mercury. Blood Wassermann 4 plus. Onset of tabes 2 years ago, with numbness, paresthesias, and ataxia; later had gastric crises, and bladder disturbances.

Physical examination: Slight ptosis of both lids; pupils were unequal, the right being larger than the left. Both were irregular, and the right reacted faintly to light while the left was completely fixed to light. His ankle and knee jerks were absent on both sides; there was moderate hypotonia and sensory disturbances of both legs; there was a well-defined Romberg and ataxia. After 3 months' treatment this patient was discharged cured of his ataxia.

Case VIII.—S. D., 42; married; merchant. Treated February, 1917. Chancre 25 years ago; no treatment. In 1913 he received 4 intravenous injections of salvarsan; 3 more in 1915. Onset of tabes 5 years ago, with shooting pains in the legs; 1 year later suffered from numbness, paresthesia, and became ataxic; later he had bladder disturbance and loss of sexual power Blood Wassermann 4 plus.

Physical examination: Ptosis of the left lid; bilat-

Fig. 7.—Case III, same as shown in Fig. 6, after the patient had received fifty reeducational treatments.

eral Argyll-Robertson pupils; knee and ankle jerks absent; marked hypotonia, sensory disturbanee and

Fig. 8.—Case IV. The picture at the left was taken in the office by artificial light, and was given a thirty-second exposure. It demonstrates very well the marked instability of this patient before treatment was instituted. Even with the aid of his stick it was impossible for him to remain steady for so short a time as thirty seconds. The next picture was taken at the same time, but is only a fifteen-second exposure, with the support of his stick. It shows the broad base assumed by the patient when standing, the distortion of the body and neck, outward rotation of the left foot, and the tremendous effort required for him to stand that short period of time. The picture on the right was taken after the patient had received twenty reeducational treatments, extending over a period of about six weeks.

ataxia. After 4 months of treatment he was able to walk in public without aid.

Case IX.—J. G., 40; married; merchant. Referred by Dr. H. Morgenbesser. November, 1914. Chancre 20 years ago; was treated with potassium iodide for

6 months. Four intravenous injections of salvarsan were given in 1913. In 1914 he received 12 intravenous injections of salvarsan. Onset of tabes 10 years ago, with shooting pains, numbness, and paresthesia; legs became tired easily; 6 months later became ataxic and progressively grew worse until he had to be supported on both sides when he walked.

Physical examination: Ptosis of the right lid; bilateral Argyll-Robertson pupils; ankle and knee jerks lost on both sides; moderate hypotonis and sensory losses; well-defined Romberg and ataxia. In 6 months he was free from his ataxia and was able to walk 2 miles without aid.

Case X.—H. E. S., 57; married; salesman. Referred by Dr. I. Strauss, February, 1919. Chancre 25 years ago; was treated with mercury and potassium iodide for three years. For the past 5 years has received 6 intravenous injections of salvarsan each year. Onset of tabes 10 years ago with fatigue, shooting pains, and slight difficulty in gait. Three years ago vision in his right eye began to fail; at this time he had some difficulty in micturition. About 2 months ago again began to have difficulty in walking, which rapidly grew worse.

Physical examination: Bilateral primary optic atrophy; right pupil larger than the left, both irregular and fixed to light. Ankle and knee jerks absent on both sides. Moderate hypotonia, Romberg and ataxia. This patient received treatment for 6 weeks and was discharged free from his ataxia.

Case XI.—S. W., 47; married; clerk. Referred by Dr. W. J. Maloney, July, 1914. Chancre 19 years ago; treated for 2 months. Eighteen months ago he received 6 intravenous injections of salvarsan. Onset of tabes about 5 years ago, with shooting pains, fatigue and ataxia. Failure of vision in the right eye; diplopia and severe gastric crises. Later had bladder disturbances and loss of sexual power. Wassermann 4 plus.

Physical examination: Ptosis of the left lid; bilateral Argyll-Robertson pupils. Primary optic nerve atrophy on the right side; ankle and knee jerks absent; marked hypotonia and ataxia; marked Romberg. After 3 months of treatment he was discharged cured of his ataxia.

Case XII.—J. H., 46; single; composer. Referred by Dr. W. J. Maloney, July, 1914. Chancre denied. Wassermann 4 plus. Onset of tabes 7 years ago, with difficulty in gait, shooting pains in legs, and gastric crises. Loss of sexual power and bladder disturbances.

Physical examination: Bilateral pinpoint pupils that did not react to light; both were irregular. Ankle and knee jerks absent on both sides. Moderate hypotonia and sensory losses. Marked Romberg and ataxia. This patient was cured of his ataxia in 8 weeks of treatment. He also married against advice.

Case XIII.—H. L., 50; married; salesman. Referred by Dr. S. Kleinberg, November, 1915. Chancre 25 years ago; treated with Hg. and K. I. for 2 years. Onset of tabes 18 years ago, with shooting pains in legs; ataxia appeared about 15 years ago; diplopia 10 years ago; bladder disturbances, gastric and rectal crises 8 years ago; loss of sexual power and desire.

Physical examination: Bilateral Argyll-Robertson pupils; knee and ankle jerks absent on both sides; marked hypotonia, sensory losses, Romberg and ataxia. This patient received treatment for about 8 weeks, and then, very much improved, he was compelled to leave the city on account of serious illness in his family.

Case XIV.—L. L., 39; married; merchant. Treated November, 1916. Chancre 16 years ago; treated with mercury and potassium iodide for 2½ years. One year ago he received 9 intravenous injections of salvarsan. Onset of tabes 10 years ago, with shooting pains in the legs; ataxia and numbness of the extremities. Later he had bladder trouble, loss of sexual power, and loss of vision.

Physical examination: Bilateral Argyll-Robertson pupils; absence of ankle and knee jerks on both sides; marked hypotonia, Romberg, ataxia, and sensory losses. He received mental training for 10 weeks and was much improved.

Case XV.—C. P., 50, married, salesman. Referred by Dr. M. Cohen, November, 1915. Chancre denied. Onset of tabes 4 years ago with diplopia, shooting pains in legs, numbness, and ataxia. Girdle sensation around the waist.

Physical examination: Bilateral Argyll-Robertson pupils; ankle and knee jerks absent; moderate hypotonia and sensory disturbances; well defined Romberg and ataxia. This patient received treatment for 8 weeks, but on account of poor cooperation I discontinued his treatment.

THE ABUSE OF CATHARSIS AND LAXATIVES IN INFANCY AND CHILDHOOD.*

By LOUIS FISCHER, M.D.

NEW YORK.

The daily administration of laxatives and correctives to infants and children is a common practice amongst many mothers and nurses. This is well known to most physicians. Indiscriminate drugging to cleanse the intestine and empty the liver is a daily routine, and this abuse is founded on the enormous amount of advertising matter which convinces the laity of the necessity for so doing. This practice is so common that it is rare to hear of infants or children whose bowels functionate normally. Drugs and correctives are used without rhyme or reason to suit the whims or ideas of the person in charge of the infant. It is not an exaggeration to speak of this as an abuse of catharsis in children.

While the daily use of drugs may be required for a short time to stimulate the secretions and cleanse the gastrointestinal tract, it is unnecessary to continue this practice over a period of many months. In acute febrile manifestations or in toxic and septic conditions where sluggish or pseudo-paralytic functions exist, laxatives are indicated, and are urgently required to eliminate stagnant residue and fermenting particles of food and their toxins which might be absorbed into the circulation. This is especially true in intestinal intoxication, accompanied by fever, caused by excessive fat or protein feeding. In this class of cases the subnormal condition caused by the fever demands especial attention.

It is our duty as physicians to sound a note of warning to the laity that the pernicious habit of giving a daily laxative lessens the functional activity and weakens the intestinal mucosa. This will in time result in a total loss of the peristaltic waves that coarse food will produce if regularly fed. While we attain the object of cleansing and eliminating fecal particles we frequently interfere with the normal process of digestion and assimilation and deprive the system of nutrition intended for growth.

The daily use of a warm soap-water enema should also be condemned. While the enema will produce an evacuation by softening the fecal masses, the warm water relaxes the muscles of the intestines, and if persisted in will produce an atony of the intestines with a tendency to prolapse. This I have seen in a few instances. When my advice is sought concerning the use of an enema, I advise cold water at a temperature of from 60° to 70°—not more than a pint, usually

*Read before the Section on Diseases of Children of the American Medical Association held at Atlantic City, June 12, 1919.

one-half pint—at bedtime, or about one-half hour before the second morning feeding. This cold enema has a stimulating and tonic effect and does not produce a harmful result.

The habit of adding correctives to the infant's milk daily, should be condemned. When large masses of tough, rubbery curd pass through the intestine undigested, due to excess of protein feeding, boiling the milk will soften the curd and frequently modify the constipation. The constipated stool caused by fat indigestion, known as calcium-soap stool, results from the formation of fatty acids in the stomach and intestines. When the foregoing condition exists the food must be modified, and not calomel and purgatives administered. When the food agrees and there is neither colic nor vomiting, but a gain in weight, my plan is to continue the formula, and if constipation exists, add an ounce of buttermilk whey to each feeding. Buttermilk whey is made by boiling the buttermilk and straining out the curd. One dram of the malted foods added to each feeding, or a dram of malt-soup will modify constipation.

The importance of water is not sufficiently emphasized. In giving a drink, not boiled water nor pasteurized water, but pure, filtered, cool water is required. Invariably on questioning mothers they admit giving boiled water to their infants. I do not condemn the use of boiled water while traveling, or when using water of an unknown source. Fresh, cool water will aid in eliminating food residue if given between meals. The water added to the infant's food is not sufficient. Water should be given as a drink between meals, several times a day. When water is refused it can be rendered more palatable by the addition of fruit juices such as orange, prune, or pineapple juice. Prune juice and spinach juice should be given for their vitamine content, their antiscorbutic properties, and their laxative tendency.

Diluents such as oatmeal water, barley water, and other starchy gruels, while nutritious and valuable in modifying the casein and fat of a given formula, have not been successful in modifying constipation. Their value consists in adding more protein to the food; although flatulence and belching usually result.

The Older Child.—The mechanical stimulus, in the atonic gut, can be given to food by the addition of bran to cereals or by the use of figs, raisins, whole wheat bread, and the coarse cereals such as oatmeal. Buttermilk or fermented milk can be used to thin the gruel.

To sweeten the food, as well as for the carbohydrate value granulated sugar, milk sugar, or malted sugar (dextrimaltose), or malt-soup should be added to the milk. Vegetables such as chopped spinach or chopped string beans, and the green vegetables rather than the starchy cereals such as potato, should be given. Crackers, wheat bread, biscuits, potato, and macaroni are the foods which should rarely be fed unless mixed with a diet having a laxative tendency.

Deficient peristalsis can be stimulated in older children by colon massage, gymnastice, or calesthenics. In some instances gentle faradization or the high frequency current applied in two-day intervals, will aid in stimulating the internal functions and in promoting peristalsis.

In subnormal nutrition, where rachitic atony of the intestine exists, there is no drug that will aid nutrition and modify constipation better than cod-liver oil. It must be given pure. To an infant six months of age, 3 drops may be added to milk three times a day, and the dose increased until 10 drops are given three times a day. Codliver oil should be ordered regardless of the season. It is an antiscorbutic in summer as well as in winter.

Oil Injections: Olive oil may be injected by means of a glass syringe with rubber tip attached. One-half ounce of oil injected into the rectum, or, with the aid of a catheter, into the colon at bedtime will soften scybala, and in some instances promote nutrition. If left in the colon over night some of the oil will be absorbed. Oil injections should not be used oftener than every other night.

The well known results of thyroid therapy, in sporadic cretinism, and the specific action of thyroid on the constipation accompanying this disease needs no emphasis from me. The administration of ¼ grain thyroid three times a day, and gradually increasing the same until 1 grain is given three times a day, has acted beneficially in quite a number of cases.

The well known effect of pituitrin in stimulating peristalsis has led me to try it in obstinate coprostasis. Two to five minims may be given hypodermically and repeated once in twenty-four hours, for several days. Some few cases responded to this line of treatment, in other cases no benefit was noted.

Interference with normal gland activity and forcing peristalsis continuously for months, and in some instances for years will lead to intestinal atony and consequent coprostasis. We must distinguish between acute febrile conditions in which there is lessened functional activity of the intestinal mucosa in addition to deficient glandular secretion wherein therapeutic assistance is required. On one hand we have an acute febrile manifestation in which therapeutic aid of some sort is required. In febrile manifestations therapeutic assistance is called for and must be given because of the pathological state of the system. In febrile conditions drug assistance is demanded; the choice of the drug must be left to the individual physician in charge of the case.

155 West Eighty-fifth Street.

AN HYPOTHESIS OF "HORMONE HUNGER."*

By Henry R. Harrower, M.D., F.R.S.M. (Lond.),
Los Angeles, Cal.

Certain fundamentals in medicine, as in other sciences necessarily must be based upon hypotheses, for it is not accorded to man to know all of the Creator's work. We are confident that scarlet fever, measles, and even "flu" are of bacterial origin; but we have yet to isolate and identify the offending organisms, as we have done, for instance, with the typhoid bacillus. Again the "accepted explanation" of the processes of immunity is the "side chain theory" propounded by Ehrlich;

*Read before the Medical Officers' Club, Base Hospital, Camp Kearny, California, May 21, 1919.

and today this hypothesis is as far as we can go in giving a reason for the "immunizing response" of the body and the "how" of its resistance to bacterial invasion.

The clinician has to presume many times. Facts are not always so easy to secure. On the other hand, the physiologist hesitates to presume—he must be scientific and empiricism has no place with him. Despite this it happens that neither clinician nor physiologist really understands how the hormones of the glands of internal secretion are made and used. We have satisfactorily proved their existence and that many of them are definite chemical entities, some of which already have been isolated in crystalline form. We are certain that they are secreted into the blood or body fluids and thus carried to distant organs or cells to "correlate the activities of the organ of origin with the remote but associated organ that it influences."

How these hormones are carried, whether they are produced in the same form that they are used,* and exactly how they reach the cells which they are destined to "arouse, or set in motion," is not now definitely known. We must theorize—an hypothesis is in order.

For a number of years I have been studying this subject and not a few clinical experiences with various forms of organotherapy in certain endocrine disturbances have convinced me that there are varying degrees of receptiveness to hormone stimuli on the part of various individuals. In other words, where in one instance a very rapid and remarkable result may be secured, in another seemingly similar case the reactivity of the patient differs and the results are not so good or so rapid. This has caused me to ponder on the subject and I have evolved what I have chosen to call "an hypothesis of hormone hunger" which I will attempt to explain.

Each organ of the body that is dependent upon hormone influences must have some subtle capacity to pick up the hormones from the blood as they float by. This cannot but be true, else how could the passing "chemical messengers" bring about the influence upon the organ or cell that they are supposed to affect? Not only must there be a definite capacity to pick up these hormones as they are brought to the cell by the blood, but there must be a selective capacity, for the blood contains all the hormones that we know of as well as probably a good many more that we do not know of at present. I do not feel that the imagination has to be stretched very much to presume that there is a remarkable "cellular judgment" or selective capacity to pick out the hormones that are needed—and in the amount they are needed.

It is with this particular selective power in mind that I have developed this hypothesis of hormone hunger. I contend that under varying circumstances these cells must be more active in their picking up of the passing hormones than at other times. In other words, at times a condition of hormone hunger actually must be present. Let me explain: Take as an example the thyro-ovarian interrelationship—this is, perhaps, the most thoroughly established and most easily understood. It is well known that there is a principle produced in the thyroid gland which exerts a very marked influence upon ovarian function. (It will be recalled that in myxedema there are definite functional ovarian disorders, that girls with goiter very often have serious menstrual difficulties and, finally, that the cretin, who has no thyroid gland, does not develop sexually.) Surely it is fair to believe that there is a principle made in the thyroid which stimulates ovarian function, and that this must necessarily reach the ovaries through the blood; and, of course, that the ovaries must have some means of getting hold of this hormone. If, then, this thyroid hormone passing through the ovaries in its blood supply happens to be deficient, after as much of it as can be found is taken up by the cells of the ovary, and the demand is greater than the supply, there will remain a need for that which is not present, *i. e.* the ovarian cells will be "hungry" for the thyroid stimulus. Further this "hunger" will vary, depending upon the degree to which the thyroid is functioning and the hormone needs of the ovary.

In a case with well defined hypothyroidism it is reasonable to suppose that the ovarian cells are getting along as best they can with little or none of their usual stimuli (and right here enters the fascinating study of the effects of hormone hunger upon other endocrine glands—how the pituitary, for instance, may function faster to make up for deficiencies in its associates, etc.). If we attempt to modify the clinical disturbances which result from this hormone insufficiency by means of organotherapy, the application of this hypothesis enables us to appreciate that the "hormone hunger" of these ovarian cells increases their presumed "urge" to pick out from the circulation such additional hormones as we may be able to give by mouth (and incidentally to benefit from the enhanced hormone production which follows organotherapy, upon the principle of "hormostimulation" as outlined in Hallion's law*) and to understand that this selective capacity will be the greater in proportion to the cellular need.

To put this in another way: If we give thyroid extract as a therapeutic measure in dysovarism, the ovaries are unusually interested in securing the thyroid hormone which may get into the blood, and they will select it with greater avidity, depending upon the degree of "hormone hunger" that may be present; and as soon as the necessities of these glands have been satisfied, the unusual facility with which the hormones are picked out from the blood stream will cease, and

*In 1913 I had the opportunity of doing some interesting work with Hustin in the Institut Parc Leopold, Brussels. He showed that secretin activated the secretory cells of a pancreas separated from the body—in a paraffin bath, but the most active secretin solution *had to be mixed with blood* before it would do the work.

*The "law" propounded by Hallion (*Presse Médicale*, 1912, XX, 433) explains the principle named "homostimulation." It is as follows: "Extracts of an organ exert on the same organ an exciting influence which lasts for a longer or shorter time. When the organ is insufficient, it is conceivable that this influence augments its action, and, when it is injured, that it favors its restoration." (Translation made in my book "Practical Hormone Therapy," p. 24.)

we presume that superfluous amounts of any or all of the hormones will remain in the blood either until they are used later by any organs that may be able to avail themselves of their stimuli, or are finally oxidized.

There is another phase to this matter which appears to me to be of importance, and which I think is more satisfactorily explained by this hypothesis than in any other way: We are convinced that the intimate interrelationships of the glands of internal secretion practically eliminate the possibility of endocrine disturbances involving a single endocrine gland. That is to say, when there is a disturbance of one internal secretory organ, immediately there develops an associated functional derangement of the hormone balance, involving one or more of the glands most intimately dependent upon the originally affected gland. Hence pluriglandular disturbances are the rule, and, therefore, pluriglandular therapy must take the place of the old-fashioned administration of the most obviously needed glandular extract. As yet this position is not generally accepted, and some members of the profession still assert that this is "shot gun therapeutics." Others, whose clinical experience and view-point are broader, now insist that in the combining of various related glandular products we are finding much greater clinical satisfaction—and the "crucible of the clinic," as George W. Crile calls it, is the only real test of any new or modified therapeutic measure. In passing, take as an instance the cretin, who it is well known is in dire need of the physiological stimulation resulting from the thyroid hormones. Many times a cretin develops remarkably on thyroid alone, and then reaches a seeming barrier beyond which no progress is made. If then the associated glands, especially the anterior pituitary, is given *with the thyroid*, the progress is reestablished and sometimes far excels that previously made. This also applies with equal force in many other pluriglandular dystrophies, the most common of which is the thyro-ovarian dysfunction already mentioned.

This brings me to my final point this evening: This hypothesis of hormone hunger explains the "how" of pluriglandular therapy. Many times I have wished that it were possible to determine the degree of glandular insufficiency in a given individual, just as we can estimate the urinary solids and differentiate the percentages of urea, chloride, phosphates, etc., in figures, or as we do in the differential blood count. It would be ideal to be able to establish that for example, a given case is 50 per cent. low on thyroid, 35 per cent. low on ovarian, and 20 per cent. low on pituitary hormone functioning! Obviously this would facilitate a definite therapeutic recommendation; but we cannot do this, although my Thyroid Function Test (see MEDICAL RECORD, August 3, 1918) is quite a step in this direction in the study of one of these dyscrinisms. How, then, can we treat these cases scientifically? We cannot; but by depending upon the hypothetical principle of "hormone hunger" just enunciated we can offer a pluriglandular mixture *and allow the body to do its own selecting.* We can trust the organism to pick out from the menu we offer it those hormones that it needs most and, too, in the degree that it needs them. Then, based upon the previously mentioned condition which might be called "hormone satiety," the limited excess of unused hormones floats on until used up or destroyed. This explains to me the reason for the clinical experience many of us may have had with the same pluriglandular therapy in several somewhat dissimilar cases. In one case a thyroid influence predominates, in another a pituitary, and in a third an ovarian, all because in these three instances the hormone hunger made it possible to grab the various respective hormones with a greater avidity and rapidity.

Whether this hypothesis is as well founded as the Ehrlich "side chain theory" of immunity, is not for me to say. It explains many things that I have repeatedly seen in clinical organotherapy and I believe it is based on sound reasoning and worthy of your consideration. At all events this remarkable selective capacity of the hormone-influenced organs or cells is something that cannot be gainsaid; and the clinical results are certain enough, whether the hypothesis is well-grounded or not.

412 WEST SIXTH STREET.

THE TUBERCULOSIS REGIMEN.

BY JOHN B. HUBER, A.M., M.D.

NEW YORK

SOMETIME PROFESSOR OF PULMONARY DISEASES, FORDHAM UNIVERSITY MEDICAL SCHOOL; VISITING PHYSICIAN TO ST. JOSEPH'S HOSPITAL FOR CONSUMPTIVES, ETC.

FOLLOWING is a circular of instructions which I have prepared for tuberculosis patients. My colleagues would, of course, be welcome to use it in any way they might desire.

The first symptoms of tuberculosis are: (1) A cough lasting more than a month (except whooping cough, in which the cough lasts six weeks or more). Such a cough may not, of course, mean tuberculosis, but it certainly calls for a thorough medical examination. (2) Hoarseness lasting several weeks. (3) Poor appetite (especially in the morning), indigestion, loss of weight and of strength, paleness and generally run-down condition ("that tired feeling"). (4) Hawking and spitting, especially in the morning. (5) Night sweats. (6) A streak of blood in the sputum. (7) Afternoon fever, shown by flushed face and alternating with chilly sensations. The spittle has to be examined for the tuberculosis germ. But it must not be concluded that there is no tuberculosis if this germ is not found, not even after several examinations. The test is absolute if it is "positive," not so if it is "negative." In all doubtful cases the chest should be *x*-rayed.

Following are the modern principles of the tuberculosis treatment, by which most early cases can be cured, many even advanced cases arrested in their development; and by which comfort and relief can always be assured. These principles can be pointed off on the thumb and fingers of one hand.

First, there must be a careful disposal of the sputum of the tuberculous—practically the only means by which the disease is conveyed from one person to another. The handkerchief or a cloth must always be held before the patient's face when he coughs or sneezes or spits out; thus a droplet or spraying or atomizing infection is avoided. The patient's handkerchiefs, towels, linen, bed sheets and the like must be boiled by themselves before being added to the general wash. Whatever can be must be burned. The spittoon must contain some fluid (water will suffice) in order that the sputum may not dry and become incorporated with the dust. And the

spittoon when cleaned must be scalded; this will kill the tubercle bacilli, the tuberculosis germ.

Secondly, there must be rest. There is otherwise no hope for the patient's emaciated body, an organism on the verge of bankruptcy. Here is, of course, a factor difficult of management, especially among the poor (who furnish the majority of tuberculosis cases), many of whom feel that they must somehow work in order to maintain themselves and their own. And yet there has to be rest, especially when there is fever; and at least until the sufferer has recuperated from the exhaustion which has been the prime predisposition to this disease. For the tuberculosis germ fattens on devitalized tissues.

The rest has got to be absolute if the bodily temperature reaches 100 degrees by the clinical thermometer; and the bed inexorably when the fever has gone above this. The rest should, if possible, be outdoors—at least with open windows. When the air is cold warm headgear is to be worn; or the woolen "helmet" which comes down over the collar bone. And the footwear must be at least as ample and as comfortable as the headgear. The body must be abundantly clothed; there are sleeping bags made for such patients. The idea of sleep is involved in that of rest. Nowhere else should nature's soft nurse be so sedulously wooed. Insomnia is most exhausting in such a disease as this, when it is so necessary to conserve and build up the strength. Nor has any restorative ever been invented to compare with sleep. Insomnia, with fatigue and overexertion, have predisposed many to tuberculosis. We strive to induce sleep without medication if possible; it may, among other ways, be induced by drinking of hot milk after the patient has been tucked away for the night.

The *third principle* underlies the idea of what is called the "twenty-four-hour cure." It is that the patient should every possible moment, day and night, twenty-three hours anyway, breathe fresh air and be in the sunshine so long as there is a ray of it. (Of course, the excessive heat of the summer sun must be avoided.) At night, no matter how cold, the windows are to be open; nailed up, not down, if there is to be any nailing. The colder the air the surer the cure; more patients recover from tuberculosis in the winter than in the summer. Drafts are, however, to be avoided. This can be done by means of a screen, or a blanket-decked clothes-horse, appropriately placed. Only twice, from day to day, should the windows be closed. A member of the family comes in half an hour before dressing time and shuts the windows. And at bedtime the patient undresses with closed windows, and when he is snugly in bed for the night someone opens his windows for him.

The *fourth principle* calls for plenty of nutritious food stuffs, coupled with good digestion, so that all the fuel taken into the body can be converted into healthy, germ-resisting tissues. The doctor must decide details for individual cases; but, in general terms, we try for the largest amount of nourishment with the least amount of labor for the digestive tract. Thus the patient should stow away roasted or broiled meats (beef, mutton or lamb), fowl, fresh vegetables and fruits, cereals liberally mixed with cream, plenty of sugar, good butter, a generous admixture of table salt and, at or between meals (if the appetite will stand for it), from six to eight eggs and from one to three quarts of milk daily. Such indigestibles as innutritious sweets, pastries and dainties must be avoided; these interfere with normal conversion of oxygen, fluid and food into healthy organs and tissues. Between meals, at any rate, plenty of water should be drunk. For no food is absorbed that is not ultimately in fluid form. No alcohol except by the doctor's prescription.

Finally, no patient shall use medicines without the direction of his doctor. Patent medicines (which have an alcohol content sometimes as large as whiskey) must be avoided. Remember that John Barleycorn and the tubercle bacillus have ever been prime co-workers. Avoid nauseating syrups.

The patient must be obedient to his physician and persistent in every detail of the treatment outlined for him. For the time being his chief occupation must be to labor to get well. He must understand that his improvement and final recovery will depend largely on his own conduct. He must realize certainly that all cures are achieved only by team work, the doctor, the patient, and the nurse working faithfully together. In any event, the tuberculosis patient must consider, before he undertakes any business or other matter, how his chances of getting well will be affected thereby; and before proceeding further he must put the matter frankly before his physician. He must make it a habit to speak of his disease to no one except his physician or his nurse. He must ignore absolutely the advice and the prescriptions of solicitous friends and relatives. However well he may imagine himself, he must continue under his doctor's care until he has been dismissed.

A CASE OF REPEATED TOXEMIAS OF PREGNANCY.

By LUCIUS FELIX HERZ, Ph.B., M.D.,

NEW YORK.

FIRST LIEUTENANT, U. S. O. R. CORPS; ASSISTANT SURGEON, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

M. C., a young married woman consulted me on January 4, 1918, for pernicious vomiting of pregnancy. She was two months pregnant at this time, was vomiting persistently, and was rapidly wasting away, and now unable to retain even water. Medical methods had been attempted by her family physician, but without success. She had received ingluvin, bismuth, and hydrochloric acid, all without avail.

The past history revealed that she had had two similar occurrences both necessitating therapeutic abortion. Also, an appendectomy had been performed upon the patient two years before, she leaving the table in shock.

Physical examination revealed a typical pregnant uterus of two and a half months' time. Also, there was a rather marked retroversion which was more plainly evident upon later examining the nonpregnant uterus. The thyroid gland was slightly enlarged.

Operation consisted of a two stage dilatation and curettage, the cervix being very rigid. Recovery was uneventful.

On May 5, 1919, the patient again presented herself with a similar history, this time being six weeks pregnant. Corpus luteum extract was given without avail, so in view of the past history and the apparent hopelessness of continuing any pregnancy in her case, another therapeutic abortion was performed. Gastric symptoms disappeared immediately, and the patient again made an uneventful recovery.

I am reporting this as a case where upon four distinct occasions the same patient had symptoms of pernicious vomiting, and therapeutic abortion had to be performed. Still, according to our laws, it would be unlawful to give this woman "birth control" advice.

251 West Forty-fifth Street.

The Special Streptococcus of Grippe.—It is evident that in the absence of any of the known or unknown causal agencies of the pandemic attention must accrue to a special form of streptococcus as the cause at least of the terrible mortality. Hence bacteriologists are writing about the grippe streptococcus, or streptococcus pandemicus, as a new variety of pathogenic organism. Whether the germ thus acknowledged is always one and the same does not yet appear. Segale writes at great length of the streptococcus pandemicus as a new organism and invests it with special cultural and tinctorial tests which are much too numerous to enumerate. The relations with other forms, especially of the streptococcus hemolyticus, are not stated. Naturally many unicists see in the streptococcus pandemicus only the ordinary cause of streptococcus sepsis.—*Pathologia.*

Medical and Surgical Lessons of the War.

DERMATOSES OF THE WAR.

By H. MacCORMAC, M.D., F.R.C.P.,
LONDON.
ASSISTANT PHYSICIAN, MIDDLESEX HOSPITAL; ASSISTANT PHYSICIAN FOR DISEASES OF THE SKIN, MIDDLESEX HOSPITAL AND SEAMEN'S HOSPITAL, GREENWICH; LATE CONSULTING DERMATOLOGIST, BRITISH EXPEDITIONARY FORCE, FRANCE.

DURING the American Civil War, Munson[1] tells us, affections of the skin were common and prevalent. He records that 30,080 cases were diagnosed as itch, and a further 35,667 were simply classified under the more general heading of skin disease; the pathology of this army itch was much disputed at the time, but as it responded to sulphur, sulphide of lime, kerosene, and other remedies of known value in the treatment of scabies, its nature seems clear.

This quotation has been selected because it will prove of particular interest to the readers of an American medical journal. But the conditions to which it refers are not unique; the same story appears again and again in military history, and when the records of the present war have been compiled it will be found that disorders of the skin, especially those caused by animal parasites, have once more been common and have occasioned much wastage.

Complete figures are not as yet available; however, here and there it is possible to obtain records indicating the extent and degree of these affections. For example, in the Report of the American Red Cross Commission on Trench Fever, Major Strong[2] quotes as follows: "McNee points out that the ravages of trench fever are among the most serious resulting from sickness, and that the most common diseases are scabies, infections of the skin, and pyrexia of unknown origin, of which trench fever constitutes the great majority of cases. These, he says, cause about 90 per cent. of all sickness in one of the British Armies."

This amazing figure will cause no surprise to those with long experience in France. Put into other words, it means that nearly 90 per cent. of all sickness arose directly or indirectly from the action of animal parasites on the skin; to the itch mite are to be attributed scabies and a large proportion of the impetigos; the louse causing trench fever and a moiety of the impetigo, and much myalgia, which was indeed often a mild or relapsing attack of trench fever.

It might be thought that at the base these parasitic affections would be of less magnitude; while this is true to some extent, an examination of the following figures representing all admissions into the Skin Hospital during one month, shows how important and considerable they were:

Scabies	571 cases
Impetigo	624 cases
Seborrheic eczema	226 cases
Boils	192 cases
Psoriasis	55 cases
Eczema	34 cases
Herpes zoster	20 cases
Syphilis	13 cases
Ringworm	9 cases
Various	42 cases
Total	1,786 cases

About one-third of the whole is made up by scabies; as severe secondary infection was present in all but ten, the total number of cases of pyodermia amounts to: 561 (scabies), 624 (impetigo), and 192 (boils), *i.e.* 1,377 out of the 1,786.

Much the same proportion and incidence obtained in the American Army, so far as can be ascertained from available information. The figures given below, supplied to me through the kindness of Major Mook, M.C., U. S. A., are taken from the records of an American Dermatological Department under his charge. Out of 2,155 cases, 1,070 were admitted with scabies and 936 with pediculosis, the balance being completed by small groups of different types.

We have learned from history that sickness always exacted a heavy tribute from armies, and knowing this military surgeons have striven to prevent the two most notorious diseases, typhoid and typhus, and with complete success in the recent war. But the same happy results have not been achieved in dealing with skin diseases and their effects, so that, it may be, medical historians of the future will give to them the place occupied by typhoid and typhus in past campaigns as a cause of wastage. As it cannot be pleaded that the results of parasitic skin disease were either unexpected or a new problem, some reason must exist to account for the attitude assumed towards them. The explanation lies, curiously enough, in the employment of a term. A group of conditions, such as minor wounds, scabies, etc., were labelled trivial diseases, and as applied to the individual such a classification was appropriate. But in estimating their effect the term was entirely misleading, because, for military purposes, the effects of any disorder should be reckoned by the wastage it occasions to the army as a whole. A simple example may be chosen to illustrate this point; if ten men contract typhoid and in consequence remain away from duty for a hundred days, a loss of one thousand fighting days ensues; if at the same time one hundred other men get itch, and each requires twenty days for cure, then two thousand fighting days will be lost. But every man removed from duty, it matters not from what cause, is equally a loss to the fighting force; when it is remembered that the general health of the men with itch remains good during the whole time, their absence is the more to be regretted. Therefore, from the strict point of military efficiency particular attention should be given to "trivial" conditions as they repay best in the results obtained. It is not meant by this that any aid science or art can afford should be withheld from the seriously wounded or sick men. Such a position is unthinkable. But strange though it may appear the "serious case" would actually benefit by more careful attention to the "trivial" conditions, because scabies—and pediculosis though to a less extent—being largely preventable, their elimination or diminution by organized effort must so lessen disease that numerous medical officers, personnel, and beds would be set free, to the great advantage of the remaining patients.

Seeing that in great wars parasitic skin disease has been of such magnitude and has caused so much loss of man-power, it may be asked can this pest be diminished, and if so in what manner? Obviously the problem is beset with difficulties, and while

theoretical solutions may be formulated, their application is not always easy or even possible under the rude conditions of active service.

In the first place it is essential to recognize that while scabies and pediculosis have much in common, there are also so many complete differences that separate plans of attack must be formulated for each disorder.

To make clear these distinctions, it is necessary to refer briefly to a few points in the life histories of the two insects. In scabies, as is well known, the impregnated female forms a tunnel beneath the skin in which she lays her eggs and from which she never again emerges. The louse, on the other hand, wanders freely over the body, the female depositing ova on the clothing, especially about the seams. It may also be mentioned here that the *body louse* can and does lay eggs on the pubic and axillary hairs, but for the moment this need not be considered.

The essential differences between the two infections may then be broadly summarized as follows: In scabies the important insect—the impregnated female—is so imprisoned that she cannot transfer herself to another host; nor do the free acari show any tendency to wander from one individual to another across any intervening space. Hence *to acquire scabies prolonged and intimate contact with an infected person or material is essential*, and this fact cannot be emphasized too strongly. The louse, on the other hand, crawls from man to man, the process being especially favored by crowding. Any insects dropped in the straw of dwellings such as dug-outs may attach themselves to those coming near them. Thus one lousy soldier is capable, under favorable conditions, of infecting many of his comrades. In contradistinction to this, one healthy individual may live with a company of scabid soldiers and never contract the disease unless he sleeps in their blankets or wears their clothing.

There is a further distinction to which attention should be drawn. As the ova in pediculosis are present on garments, etc., much more elaborate methods for disinfection of such materials are necessary than in the case of scabies where the ova lie beneath the patient's skin and are destroyed during treatment.

It may be asked, what proof is there of the accuracy of the above statements? There is ample. That the louse can easily transfer itself from one individual to another under the crowded and dirty conditions of trench life requires no further discussion. That a similar easy transference does not happen in the case of itch will probably be less readily believed. Yet the truth of this was clearly demonstrated in the Skin Hospital; there no attempt was ever made to separate those with scabies from the other patients. They used the same baths and latrines, followed exactly the same mode of life, and associated in the most complete manner both in their tasks and recreation. Despite this, cross infection did not occur. Nor did any nursing sister or orderly ever contract scabies, although they had to dress and look after such patients. When it is remembered that the "turnover" of the hospitals was very large, and that the observation is based on an experience extending over three and a half years, its truth may be accepted.

From these facts the obvious inference must be drawn that scabies is difficult to acquire and easy of control as compared with pediculosis, and therefore that a campaign organized against it would well repay in the results obtained. In making such an attempt special consideration should be given to the means by which itch is spread and to the methods of diagnosis and treatment.

The Means by Which Itch Is Disseminated.—Small and I[2] have pointed out in a previous paper that in the army scabies is distributed through three sources, blankets and underclothing, infected women, and "mangy" horses.

Since prolonged and intimate contact with an infected person or material is essential to acquire scabies and since such opportunities can be possible only in rest when clothing is removed, reason strongly points to the blanket, passing as it does from man to man, as a common source of disease. The fact that scabies was more common in winter confirms this view. Strangely enough, Sergeant Anton, a veteran of Wellington's army and a shrewd observer of men and things, had noted this and has recorded it in his interesting and quaint recollections. In those far-off days the married men were accompanied on service by their wives, and these poor women shared the miseries and horrors of war.

The following extract from his diary gives a glimpse of their lives and is of peculiar interest in its relation to the subject of this paper: "I now," he says, "set about erecting a hut for myself and wife, resolving if possible not to mix blankets with so many bedfellows again. This I was the more anxious to do because at that time the whole of the men were affected with an eruption of the skin similar to the itch."

That scabies may be a venereal disease is generally recognized, and upon such an origin French authorities lay great stress. While admitting that some infections may arise in this way, it would be most unjust to the patients to account thus for more than a small proportion of the cases in the British Army. Great care was taken in establishing the accuracy of this statement, and it is made with every confidence in its truth.

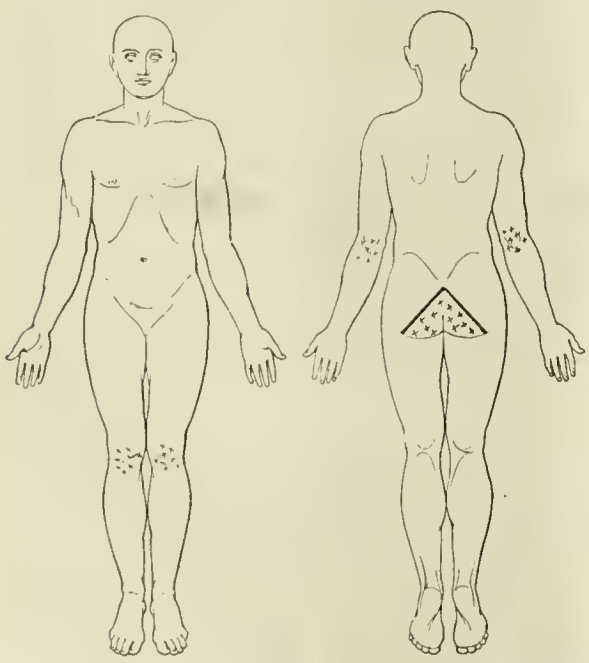
Finally, horses with "mange" may undoubtedly infect men who are in contact with them, and a remarkable instance of this came under the observation of Captain Small, R. A. M. C. From a certain A. S. C. unit a number of men were from time to time admitted with scabies. The source of this epidemic remained completely mysterious until, at Captain Small's suggestion, an inspection of the horses was carried out. Some were found to have skin disease and were removed for treatment, after which no further cases occurred among the men.

Diagnosis and Treatment.—It does not go too far to say that every problem and difficulty connected with scabies is solved by detection of the disease in an early stage. At this time secondary pyodermia and dermatitis have not as yet arisen, therefore treatment is easy and cure rapid, 3 instead of 31.7 days being sufficient. Further, and of much higher importance, as the infected man has had little opportunity to contaminate others, early detection prevents spread of the disease, as it removes the source of infection.

But early detection depends upon two factors, first, the familiarity of the medical officer with the disease in this stage, and second, frequent inspection by him of the men under his care. It is useless to depend upon the soldier to report early, he invari-

Fig. 1.—Scabies; front of the wrist. The lesions have become pustular from secondary infection.

ably comes when ecthyma and boils have arisen. Undoubtedly there are times when inspections are difficult or impossible to arrange, but the energetic battalion doctor can find opportunities for performing this duty. Then he must know what to look for, and here a difficulty arises as the type met with in France differed in many essential respects from that seen in civil life. The hands were often entirely spared, and even when involved, burrows were present in only 13 per cent. of cases. Secondary pyodermia was so regularly present and usually assumed such a severe and extensive character that the underlying causal condition might be masked by it. For these reasons examination must be very complete, the man stripping to the waist and dropping his trousers to the knees. A correct conclu-



Figs. 2 and 3.—Illustrating the distribution over the knees, elbows, and "buttock triangle" of the ecthymatous lesions secondary to scabies.

sion can always be arrived at both in the primary disease and after secondary infection has occurred by simple inspections of the patient. In the primary disease the lesions, such as papules, vesicles, and burrows, are developed on the anterior axillary folds, the abdomen, the hands and wrists, feet and ankles. Multiple vesicles between the fingers and over the fronts of the wrists are of special significance. A typical example of the latter form of infection is illustrated in Fig. I. As would be expected invasion by pyogenetic organisms soon occurs.

The penis is rarely spared, an eruption in this situation being present in almost every case, occurring on the glans, prepuce, or body of the organ. This may assume the form of papules, pustules, or small scabs, and is found even when the disease is scanty or indeterminate elsewhere. If the scabies owed its origin to impure sexual intercourse, or where there was one single large scabid crust, a confusion with syphilis might occur. Apart from this source of error these penile lesions prove of the greatest assistance in forming a diagnosis. They enable a distinction to be made between scabies and

Fig. 4.—Lacerated back, a form of ecthyma secondary to pediculosis. The distribution is characteristic.

"acute" pediculosis, where the extensive papular eruption on the trunk bears a close resemblance to itch, as in this case the penis is invariably spared. The two conditions can, and indeed frequently did, coexist.

A real difficulty arose at times in distinguishing between scabies and dysidrotic eczema; in both multiple vesicles occur between the fingers and sometimes on the wrist. Dysidrosis was relatively common during the warm season, and the two diseases might be present in the same patient at the same time. But the vesicles of dysidrosis are more deeply set and present the typical "sago grain" appearance. As will be believed, it was not always easy to convince the patient that these were eczematous, and could be disregarded, and that the scabies had been cured, and that further sulphur treatment was not only unnecessary but actually harmful.

The above shortly summarizes the main features

of early scabies, and the more common conditions liable to be associated with or mistaken for it. When secondary pyodermia arises its distribution is sufficiently characteristic to enable the observer to form a correct diagnosis and recognize the underlying scabies. The true nature of the complaint is revealed by the manner in which the ecthymatous sores—shallow crusted ulcers or erosions—are grouped over a triangle on the lower buttock, and less regularly on the elbows and knees (Figs. 2 and 3). Even when secondary infection has become widely spread and is further complicated by furunculosis this grouping can be clearly distinguished. Indeed, the association of pyodermia and scabies was so common, that at the Skin Hospital it was the rule to exclude scabies before diagnosing primary boils or impetigo. This practice was most necessary and prevented many mistakes.

Fig. 5.—Ecthyma secondary to scabies affecting the lower buttock triangle.

Of course a search should be made to confirm the diagnosis in the regions typically affected by primary scabies, especially the penis.

In consequence of the prevalence of these "irregular" forms in the army, many escaped detection and by this means the disease was spread. They were often regarded as impetigo or boils, and treated as such for long periods. No blame can be attached to the medical officer for this. One demonstration would have sufficed to arm him with the necessary knowledge; illustrative cases were always at hand, and suitable opportunities for instruction were plentiful; only the itinerant lecturer was wanted.

It is not proposed here to discuss the many ways by which scabies can be cured. For the needs of an army the chosen remedy should be cheap, reliable, and of easy application. All these requirements are satisfied by sulphur in the form of an ointment. Great advantage is derived from standardizing a method, and as it was found after extensive trial that the one to be described gave better results under active service conditions than any other, it was adopted as a routine. Since success depends on minute attention to detail and upon knowledge of the principles involved, it is essential that all stages be carefully supervised by a medical officer, for even the best orderly becomes in time irked with the tedium of the daily routine. The cure extends over three days, the procedure being as follows:

On the first day the patient, completely stripped, is rubbed with soft soap for twenty minutes, particular attention being paid to the hands, feet, penis, and axillæ. At the end of this period he enters a warm bath where he lies immersed below the neck for a further twenty minutes; during the last five minutes in the bath, the parts chiefly affected should be gently scrubbed with a moderately soft brush. Let it be noted that this soaping and soaking are intended to accomplish one purpose only, viz., the opening up of all haunts of the acarus so that the parasiticide to be used can get at and destroy insects and ova. It is the most important part of the treatment, and success depends upon the thoroughness with which it is carried out. After leaving the bath and drying, sulphur ointment (B. P.) is thoroughly

Fig. 6.—Deep sluggish ecthymatous ulcer; in the neighborhood are seen scarring and pigmentation left behind by other sores.

rubbed into the whole body below the neck, especially into the hands, feet, axillæ, and penis. By placing the men in groups and following a sort of drill it is possible to arrange that each will have his back rubbed by his neighbor, thereby saving orderlies'

Fig. 7.—Common type of ecthyma characterized by the presence of multiple shallow sores.

time and indirectly increasing the amount of treatment to the hands. Clothing is now put on and the patient returns to his ward. Where possible, cotton gloves should be worn as they retain the ointment better.

On the second and third days a similar inunction with sulphur ointment is carried out, but no bath is taken. By the fourth day it is assumed that all insects and ova have been destroyed. A second bath is therefore now taken to wash off any remaining ointment, and a complete change of clothing and bedding issued to prevent reinfection. Treatment of any existing pyodermia or dermatitis may now be commenced.

This routine is successful in curing the scabies in nearly every case. Failure is attributable to neglect of some detail. The application of the ointment must be copious and energetic. It is obviously useless to inunct limited areas; the whole body below the neck must be rubbed or some insects will escape destruction. Unless the preliminary bathing and soaping have been well carried out the parasiticide may fail to reach the parasites deep in the burrows, and relapse will occur. Clothing and bedding must be disinfected immediately the sulphur is discontinued, otherwise the patient will be in a position to reinfect himself. Finally, the ointment should be used for *three days only*. If properly applied a cure has been effected and its further employment only tends to cause dermatitis. Indeed, even when used as described above, slight dermatitis is not uncommon, and as this was associated with itching and might first appear five or six days after sulphur had been discontinued, it was frequently mistaken for a relapse of the disease. Confidence in the form of treatment employed will, of course, prevent such an error.

Every form of dermatitis in patients with scabies should not be attributed to sulphur; in some degree it was quite commonly present before any treatment had been instituted and was then no doubt due to the combined effects of the irritation of lice and acari. These facts were not as well known as was desirable, and when wrongly interpreted they were sometimes used as arguments against the method of treatment.

One further point remains to be discussed. As early diagnosis must be followed by early treatment, large centers staffed by experts should be included in every army. Here the man is sent immediately, receives complete treatment, and is rapidly returned to duty. Such a plan presents such obvious advantages that reasons favorable to it need hardly be given. It means, of course, specialism; specialism can be translated by efficiency, and efficiency results in the saving of man-power.

Pediculosis.—As has already been pointed out, lousiness is a much more difficult condition to control than scabies. A louse may actually exist separated from its human host for nearly nine days (Peacock), and as its migratory powers are not inconsiderable, it follows that the insects can readily transfer themselves to any newcomer. But, while the wandering habits of the parasite serve to spread pediculosis, the persistence of the condition depends rather upon the ova; indeed, the prolific female is able to produce 125 eggs, some of which may remain dormant, away from the body, for a period of forty days (Warburton, quoted by Peacock). It is therefore useless to cleanse a man and provide him with clean shirts and underclothing unless the ova on his tunic and breeches are destroyed. Attempts to diminish pediculosis then should aim at prevention by use of chemical deterrents, and cure by bathing the infected man and disinfecting his garments and blankets.

Probably N. C. I. powder* proved the most efficient deterrent of all those employed. Dusted on the socks, shirt, fork of the breeches, and seams of

the tunic, it kills and keeps away. But it is a powerful remedy and capable of damaging the skin, especially about the scrotum; therefore in this re-

*Naphthalene 96 per cent., creosote 2 per cent., iodoform 2 per cent.

gion an ointment is preferable, such as vermijelli, or vermijelli might be used exclusively, although it is much less potent. Other deterrents, such as mercurial preparations, are dangerous, and a peculiar dermatitis of the waist region was sometimes observed caused by the use of strings soaked in blue ointment. Sulphur, although it enjoys popular favor, was found to be quite useless.

Bathing is usually considered sufficient to cleanse the man, but observations made during the war have demonstrated that such a view is completely wrong, for it has been shown by Bulliard in the French Army, and Barber and Semon in the British, that body lice freely deposit their ova on the pubic and axillary hairs, and therefore unless measures are taken to disinfect such regions relapse will inevitably occur. This adds considerably to the difficulties of the problem. A man can, and will, carefully bathe himself, but he cannot, or will not, remove ova from these situations. In hospital this is possible and should invariably be done, but at Divisional Bathing Stations such steps are almost impossible. Let the reader visualize such an establishment, situated in an old house or rough shed, often within range of shells; the soldiers are hurrying through the baths in batches, after discarding their soiled shirts and underclothing in bins, their tunics and trousers being ironed the while, or passed through a disinfector. What an army of orderlies would be necessary to complete the pubic and axillary toilet!

Although the methods whereby garments and blankets may be disinfected are clearly understood, for obvious reasons the carrying out of such processes cannot always be easy. A steam pressure apparatus must operate for one-half to three-quarters of an hour, during which time the man is parted from tunic and breeches. Ironing also requires a number of assistants equal in strength to the bathers if all seams are to be thoroughly treated. For isolated units disinfection may be accomplished by strong cresol solution or boiling water, but this method is not suitable for general use.

These difficulties stimulated individual ingenuity and consequently many simple devices for delousing were invented. Nearly all were based upon disinfection by means of hot air, the dirty material being exposed in special chambers, boxes, or earthen trenches, to a temperature of 70° C. to 90° C. for twenty minutes, which was found sufficient to destroy both insects and eggs.

But despite the advantages in knowledge and improvements in technique, the problem of pediculosis was by no means solved. Even when the man had been thoroughly disinfected he could hardly hope to escape reinfection, so easy was contamination. A condition of cleanliness means freedom from lice, and this, while theoretically simple, in practice proved extremely difficult or impossible to attain. It is an old problem reintroduced amidst new surroundings.

Our ancestors were often familiar with these little friends. Baths and soap have succeeded in banishing them from cleanly people, and it is unlikely that the war will cause any considerable or permanent increase in pediculosis among the civil population as it has done in the case of scabies.

The "Impetigos."—The group of dermatoses included under this heading were so important and common in the army as to merit special consideration. Before describing the four main types individually some general remarks are called for.

Impetigo, as is well known, results from streptococcal infection of the skin. While this can, and often does, arise primarily, it is also often associated with, and follows upon, some other complaint such as scabies, or pediculosis. It is essential to bear this fact constantly in mind. In such cases the impetigo arises upon healthy skin, but it may also be grafted upon some preexisting dermatosis—especially seborrheic eczema—in which case it may mask and conceal the primary disorder; this process is termed impetiginization, and is not uncommon both in civil and military practice; if imperfectly understood it is apt to cause confusion and lead to the employment of unsuitable remedies.

Consideration of these facts suggests the natural division of the "impetigos" into four separate groups:

1. Impetigo contagiosa.
2. Ecthyma, or deep impetigo.
3. Impetigo secondary to scabies.
4. Infected, or impetiginized, seborrheic dermatitis.

1. *Impetigo Contagiosa.*—This complaint is so common among the poorer classes in civil life and appears with such unfailing regularity in the outpatient department of hospitals that it has become a familiar object to all medical practitioners. The elementary lesion consists of a delicate vesicle or bulla, so tenderly constructed that it ruptures if subjected even to a trifling trauma. For this reason the early stage is seldom seen, the disease more commonly presenting itself when the bulla has been replaced by an extremely superficial "stuck on" crust. On removing this a raw, moist, smooth surface is exposed, features which are of diagnostic importance. Since the disease results from streptococcic inoculation, it arises most often on exposed parts such as the face and hands. Contrary to what might be expected, it was comparatively rare in France, although suitable conditions existed there for its occurrence and spread.

Treatment is simple and cure rapid; after removing the crusts with cold boric-starch poultices or fomentations, the sores should be anointed with zinc ointment containing 1 per cent. ammoniated mercury.

2. *Ecthyma* differs from the above in degree only, the process extending to the dermis instead of being limited to the epidermis. Because of its deeper nature it pursues a prolonged course and tends to leave scarring and pigmentation behind. Ecthyma was so common in France that it is certain many men will leave the army with these pigmented scars, a point worth noting since their resemblance to late syphilitic manifestations is close enough to lead an observer into clinical error. As in the case of impetigo contagiosa, ecthyma is primarily represented by a bulla. This is succeeded by a shallow ulcer or erosion covered by a dark scab. The formula "I. C. T." (inflammation of connective tissue) was commonly applied to this condition, although it was also used as a designation for boils, cellulitis, and pyodermia of various types. It was

an unfortunate term, for it embraced so many things that it came to have no precise or useful meaning.

Ecthyma was often due to scabies, and also frequently followed pediculosis. So many severely in-

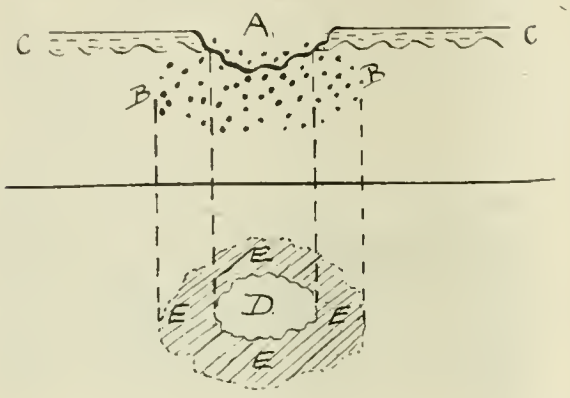

Fig. 9.—Plan and elevation of ecthymatous lesion, showing the sore from above (D), with its halo (EEEE), and same sore in section (A) with inflammatory cellular reaction (BB) and normal skin (CC).

fected men remained completely free that it is difficult to decide just how far pediculosis and ecthyma were related as cause and effect. The disease resulted from streptococcal inoculations and might follow any form of rubbing or scratching. A common form is depicted in Fig. 4. Here the torn and lacerated flesh clearly proclaims its louse origin. Note should be taken of the distribution over the upper buttocks and lumbar region. This is quite different from the form associated with scabies where the lesions affect the lower buttock triangle as shown in Fig. 5.

Ecthyma was a very real cause of disability; this is evident from the accompanying photographs. Fig. 6 shows a single deep ulcer on the leg and some pigmented scars left by other healed sores. Such ulcers were sluggish and extremely rebellious to treatment; they were found both in young adults and older men and were unconnected with varices. The commonest type of ecthyma is illustrated by Fig. 7; it is characterized by the presence of multiple shallow sores, scattered over the legs, body, and arms; these might be very numerous, and autoinoculation was frequent and extremely difficult to prevent. As may be imagined, the labor involved in dressing such cases was considerable. Fig. 8 represents a third variety where scratching and rubbing had been obviously a prominent feature. About the middle of the leg a boil has developed, and this association was common in all varieties. Many such "boils" were undoubtedly of streptococcal origin. They began as a bulla around a hair follicle, were often accompanied by lymphangitis, or even by adenitis of a sufficiently severe nature to require incision and drainage. They pursued a much more acute course than the common furuncle and represent a distinct type.

In the treatment of ecthyma, fomentations are first used, then lotions, and finally ointments. The reasons for these steps are shown in Figure 9. This "plan and elevation" represents an ecthymatous sore seen in section (A.B.C.) and from above (D.E.). The ulcer (A), covered by a crust, and containing pus, is surrounded by a zone of cellular exudate and vascular dilatation (B) resulting from the streptococcal invasion. This inflammatory reaction translates itself upon the skin by a bright red halo (EEE), surrounding the sore (D), and the vividness of this halo indicates the degree of the progressive phase of the infection; it is evident that external applications can have little influence in controlling this process, and that a condition of stability may be best obtained by assisting the natural reaction. This is accomplished by fomentations which promote drainage, open up channels, and generally help the action of the normal antisubstances. Fomentations therefore should be employed while the halo is still vivid, that is for about two days. Of course mechanical removal of crust, and cleaning of the ulcer with antiseptics are first carried out, and the general rule of washing the skin with 1 in 1000 perchloride lotion before applying a fomentation should not be neglected or autoinoculation may occur in new areas.

By these means the acute process begins to subside, the halo darkens and fades; now wet dressings or ointment can be applied. In this quiet stage excellent results may be obtained by painting the sores with a solution of sweet spirit of nitre containing 15 grains of silver nitrate to the ounce, and thereafter covering each lesion with 2 per cent. ammoniated mercury in zinc ointment.

It is a good plan where extensive disease exists to give the patients a daily cresol bath, using 2 to 4 drachms of cresol to 30 gallons of water.

3. *Impetigo Following Scabies.*—Concerning this form of impetigo enough has already been said to render further particular description unnecessary.

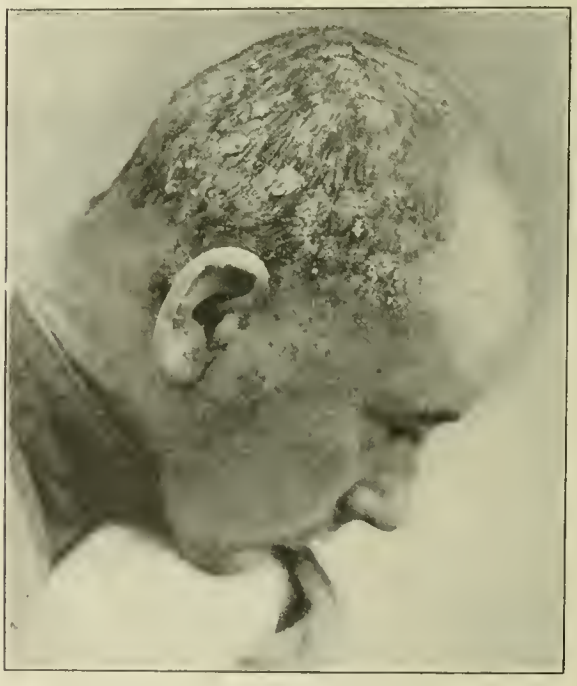

Fig. 10.—Early eczematization of the scalp. The seborrheic process has changed into a weeping eczematous surface.

It will be remembered that the lesions group themselves over the lower buttock triangle, the elbows, and the knees; that they are of an ecthymatous nature, and that no attempt should be made to cure them until the scabies has received treatment. They

are then dealt with exactly in the manner described above, and present no novel or peculiar features.

4. *Impetiginized or Infected Seborrheic Eczema.*—Among British troops, seborrheic disorders were peculiarly prevalent, such as pityriasis of the scalp,

FIG. 11.—Seborrheic dermatitis. Here impetiginization has been added to the eczematization, producing a condition closely resembling impetigo.

the circinate or follicular eruptions of the chest and back, and the flexural dermatitis of the groins and front of the elbows. Although in many instances they persisted indefinitely in a quiet phase, in others an eczematization occurred, the lesions becoming moist, weeping, and crusted. This eczematization was especially common about the head and face, and as the moist surfaces resulting therefrom formed a particularly suitable soil for streptococcic growth, a further process, an impetiginization, was frequently superadded. This complex process of eczematization *plus* infection produced a picture which mimicked impetigo contagiosa so closely that it was almost invariably mistaken for it. Three photographs are reproduced to illustrate these appearances. Fig. 10 is an example of moderately early eczematization of the scalp. Here a moist condition with scaling and flaking has replaced the common dry disease. Infection is already present about the ears. In Fig. 11 a further stage is shown; impetiginization has spread over the face widely, affecting the eyebrows, cheeks, chin, and ears. Especially confusing are those cases where infection is localized and restricted to a small area as in Fig. 12. But even here a distinction can be made by observing that the crusts are not merely "stuck on" as in the case of impetigo contagiosa, but firmly attached, and when removed disclose an irregular surface. In the more extensive cases diagnosis is established by noting the distribution, the lesions forming on hairy regions, the scalp, eyebrows, cheeks, and chin, producing in this way a very characteristic pattern. A further point should be noted: where the head and face become severely involved the ears rarely escape, and as the morbid process frequently extends along the meatus, a purulent discharge is set up. This combination of a running ear with periauricular skin disease naturally tempts the observer to diagnose middle ear disease with secondary impetigo. The history of the two conditions, however, is different, the running ear of seborrhea following, not preceding, the skin affection.

The strongest proof of the accuracy of these views is found in the response of the disease to treatment. Dealt with as an eczema it gets well: when mercurial ointments are employed it spreads, weeps, and sometimes becomes almost unbearably irritable.

Treatment: Of all remedies employed calamine liniment proved best. The formula is as follows:

℞ Calamine ..... gr. xx
Zinc oxide ..... gr. xv
Lime water ..... ʒii
Olive oil ..... ʒi

To obtain the maximum benefit certain rules should be followed. In the first place, it is useless employing any remedy over crusts, therefore these must be removed by cold boric-starch poultices; clipping of hair is also desirable. These steps enable the remedy to come into close contact with the diseased surfaces. The liniment is applied to the

FIG. 12.—Impetiginization limited to a small area. The distinction of this variety from impetigo contagiosa is particularly difficult.
